Table S1: Summary of infection gene expression time-series data sets analyzed. All host cells in the experiments were human primary or cell-culture derived.

Nau et al. exposed primary human macrophages collected from different donors to a variety of live bacteria and bacterial cell components [1]. The macrophages were exposed to the infectious agent or component for twenty-four hours, and four to five time-points were collected. Organisms included representative species from the major classes of human bacterial pathogens: Gram-positive organisms (Staphylococcus aureus and Listeria monocytogenes), Gram-negative organisms (Escherichia coli, enterohemorrhagic E. coli O157:H7 [EHEC], Salmonella typhi and Salmonella typhimurium), and Mycobacteria (Mycobacterium tuberculosis and Mycobacterium bovis). The macrophages were also exposed to bacterial cell components, including those specific to Gram-negative organisms (lipopolysaccharide [LPS]) or Gram-positive organisms (lipoteichoic acid [LTA] and protein A), and components common to all three classes of bacteria (heat shock proteins [hsp65 and hsp70], muramyl dipeptide [MDP], formyl-methionine-leucine-phenylalanine [f-MLP] and mannosylated proteins [D-(+)-mannose]).

In a follow-up study, Nau et al. exposed human macrophages to five different immune-modulating molecules [2]. The molecules used were: interferon-alpha (IFN-α), interferon-beta (IFN-β), interferon-gamma (IFN-γ), interleukin 10 (IL-10) and interleukin 12 (IL-12). The macrophages were exposed for twenty-four hours and five time points were collected.

Huang et al. exposed primary human dendritic cells collected from different donors to several live infectious agents and relevant components of the agents [3]. Dendritic cells, which reside in tissues in an immature state, are involved in initiating both innate and adaptive immune responses. They recognize and phagocytose antigens, which then leads to their maturation, expression of co-stimulatory molecules, and subsequent interactions.
with naive T-cells. Dendritic cells were exposed to representative organisms and relevant components: bacteria (*E. coli* and LPS), fungi (*Candida albicans* and mannan, a fungal cell-wall component) and viruses (Influenza A and synthetic dsRNA). Cells were exposed for twenty-four or thirty-six hours, and seven to eight time-points were collected.

Boldrick *et al.* exposed primary human peripheral blood mononuclear cells (PBMCs) from different donors and cell-line derived macrophages to several heat-killed and live bacterial pathogens, a bacterial component, avirulent bacterial strains, and immunostimulatory chemicals [4]. Cells were exposed to heat-killed *E. coli*, *S. aureus* and *Bordatella pertussis* bacteria for six, twelve, or twenty-four hours and five to seven time-points were collected. Additional experiments were done using live virulent *B. pertussis*, avirulent strains, and LPS from the virulent organism. Additionally, cells were exposed to ionomycin and phorbol 12-myristate 13-acetate (PMA), chemicals that induce cellular responses mimicking antigen exposure. The authors noted that heat-killed strains were used to reduce confounding effects from differential bacterial growth rates and cytotoxic effects on host cells. *B. pertussis* was chosen for live infections, because this organism is relatively slow-growing and is not known to cause significant cytotoxicity. The authors additionally noted that the use of peripheral blood mononuclear cells, which consist of diverse cell populations involved in both innate and adaptive immunity, had advantages because interactions among different immune cells might be observed.

Pathan *et al.* exposed whole human blood cells from two donors to the live pathogenic bacteria *Neisseria meningitides* [5]. Cells were exposed for twenty-four hours and five time-points were collected.

Guillemin *et al.* exposed cell-culture derived human gastric epithelial cells to the live pathogen *Helicobacter pylori*, a leading cause of peptic ulcers [6]. Cells were exposed for twenty-four hours and five time-points were collected. Guillemin *et al.* also exposed cells to four different *H. pylori* mutants deficient in various genes of the *cag* pathogenicity island, a contiguous collection of genes that confer virulence properties. Unlike the host cells used in the other data sets described above, gastric epithelial cells are not involved in principle immune system functions.
