S6 Fig. DNA methylation (DNAm) of age-associated CpGs in AML samples with IDH2 or WT1 mutations.

These heatmaps demonstrate the age-associated CpGs that are either hyper- or hypo-methylated in normal blood (corresponding to Fig 1D). DNAm levels are exemplarily depicted for subsets of AML patients with either IDH2 mutations (A) or WT1 mutations (B). Please note that CpGs with age-associated hypermethylation (purple) are also higher methylated in patients that are predicted to be older, whereas this was not observed for hypomethylated CpGs. Thus, our findings cannot simply be attributed to global DNAm levels or mutation specific signatures that are caused by different mutations.
