Introduction

The traditional approach to modelling of biological reaction networks is based on deterministic mass action kinetics in which the time course of the species concentrations averaged over the population is described by a set of coupled ordinary differential equations [1], often referred to as the macroscopic rate equations. For the description of intra-cellular processes characterized by a low number of reacting molecules the stochastic modelling approach [2] is an alternative that explicitly takes the discreteness and stochasticity of chemical kinetics into account. In well-mixed conditions the system dynamics are captured by the Kolmogorov differential equation, also referred to as the chemical master equation, for the transition probability kernel of a continuous time Markov process with discrete state space. Numerical solutions of the master equation, even after projection to finite state space [3], are computationally expensive, but realizations of the stochastic process can be achieved by the Gillespie algorithm and its variants [4], [2]. A stochastic differential equation approximation to the true process is given by the chemical Langevin equation [5], the associated Fokker Planck equation then describes the probability density function of the continuous state variable. An alternative approximate description is the linear noise approximation [6] that features a partial differential equation for the probability distribution of the fluctuations around the deterministic part governed by the macroscopic rate equation.

Parameter estimation in differential equation models is a classic nonlinear inverse problem that arises in a variety of scientific, industrial and financial applications and is approached both in deterministic and statistical ways [7], [8], [9], [10]. The advances of experimental biology even at the single cell level [11], [12] along with the ever growing quality and amount of species concentration data have also stimulated recent interest in the inference of reaction rate parameters in kinetic biological models. A common feature of many parameter estimation methods is the comparison of time series data with parameter-dependent model predictions. For instance, [13], [14], [15] compare time series data with the solution of the macroscopic rate equation in the minimization of unregularized and regularized least squares functionals, approximating posterior distributions or sequentially processing the data. In this article we assume that the biological reaction network can be observed at least partially and repeatedly over time such that sample moments of species molecule numbers for various time points can be calculated from the data. Based on the chemical master equation we furthermore derive closed systems of parameter dependent nonlinear ordinary differential equations that predict the time evolution of the statistical moments. For inferring the reaction rate parameters we suggest to not only compare the sample mean with the theoretical mean prediction but also to take the residual of higher order moments explicitly into account. Cost functions that involve residuals of higher order moments may form landscapes in the parameter space that have more pronounced curvatures at the minimizer and hence may weaken or even overcome parameter sloppiness and uncertainty. As a consequence both deterministic and stochastic parameter inference algorithms may be improved with respect to accuracy and efficiency. We demonstrate the potential of moment fitting for parameter inference by means of illustrative stochastic biological models from the literature and address topics for future research.
inference, [20] compares probability density or cumulative density functions obtained from the data with their counterparts constructed from repeated realizations of the Gillespie algorithm, and [21], [22], [23] sequentially compare time series data with the solution of the macroscopic rate equation when applying extended Kalman filters or nonlinear observers. For inferring the rate parameters $q$ from a time series data vector $x$, some of the available approaches explicitly take parameter dependent predictions of the mean $\mu^q(t)$ (the first moment) as well as of higher moments, e.g., of the variance $\mu^2(t; q)$ (the second central moment), of the state variable $x(t; q)$ into account, for instance, for building the (simplified) likelihood function
\[ L(q) = \prod_{i=1}^{n} \frac{1}{\sqrt{2\pi\mu^2(t_i; q)}} \exp \left( -\frac{(x_i - \mu^1(t_i; q))^2}{2\mu^2(t_i; q)} \right) \]
for a multivariate normal distribution or a weighted sum of squared residuals
\[ SS(q) = \sum_{i=1}^{n} \frac{(x_i - \mu^1(t_i; q))^2}{\mu^2(t_i; q)} \]
see [24], [19], [16], [25]. However, an adjustment of model parameters in order to actually also fit higher sample moments derived from time series data, e.g., by computing the distance between the sample variance $\mu^2$ and the variance model prediction $\mu^2(q)$, so far has - to the best of our knowledge - not been considered. Furthermore, studies of parameter sensitivities and identifiability [26], [27], [29], [29], [30] typically are based on macroscopic rate equation models where the Hessian matrix of $-L(q)$ or SS($q$) (usually with $\mu^2(t; q)$ replaced by parameter independent weights) to be analyzed involves only a comparison of the data $x_i$ with the first order moment $\mu^1(t_i; q)$. Small or zero eigenvalues of the Hessian at a minimizer point to small or even vanishing curvatures of the landscape function in parameter space, a situation called parameter sloppiness [27] as parameters then are only poorly constrained by the data and not uniquely identifiable.

Parameter sensitivities have also been studied for stochastic chemical kinetics models [31] based on the linear noise approximation, still the distance between sample and theoretical moments is not part of this analysis. Finally, the design of experimental stimulation protocols for improving the parameter identifiability in macroscopic equation models has been studied in [32].

In this paper we present a moment fitting approach to parameter inference in stochastic biological models from time series data that to the best of our knowledge has not been studied before. First, we focus on a comparison of probability density functions rather than on a comparison of statistical moments, model predictions based on the above mentioned ODE system are computationally much cheaper than those based on repeated realizations of the Gillespie algorithm. Analytic expressions for the steady state mean and variance of a scalar variable have been used in [35] in order to obtain initial guesses for a parameter inference routine based on comparing experimental histograms from stationary data with model predictions. Still, the latter are obtained as in [20] from repeated simulations of the (stationary) chemical master equation. The moment fitting approach presented in our paper handles time series data and involves only the solution of a single moment ODE system rather than repeated stochastic simulations. This reduces the computational costs and allows one to build parameter sensitivities for gradient based optimization and solution analysis. In a sequence of illustrative examples with simulated data from the literature we demonstrate potential benefits of our approach and address future challenges.

### Results

We studied the concept of moment fitting for parameter inference in stochastic biological models from time series data by means of three reference examples, see Materials and Methods for all model details, and chose $k=2$ as highest order in all of our tests.

#### Results for Linear Birth and Death Process

The Kolmogorov differential equation (11) in this example reads as
\[ \frac{d\pi}{dt}(x,t) = q_1(x-1)\pi(x-1,t) - (q_1 + q_2)x\pi(x,t) \\
+ q_2(x+1)\pi(x+1,t) \]
and implies the ODE system
\[ \frac{d\mu^1}{dt}(t) = (q_1 - q_2)\mu^1(t), \quad \mu^1(0) = x_0 \]
that describe the time evolution of parameter dependent moment approximations $\mu^q(t)$ up to the order $k$ and can be obtained from the chemical master equation via moment closure techniques, the Fokker Planck equation or the linear noise approximation [37], [38], [39], [40], [41], [42]. Now, let $\mu^q(t)$ denote those components of $\mu^q(t)$ that depend only on the observable state variables. For solving the parameter inference problem we then suggest to utilize the distance $d(\hat{\mu}^q, \mu^q(t))$ between the sample moments $\hat{\mu}^q$ and the equation output $\mu^q(t)$ in global and local minimization techniques or approximate Bayesian methods. For $k>1$ the span of the eigenvalues of the Hessian matrix of $d(\hat{\mu}^q, \mu^q(t))$ may be strongly reduced in comparison to cost functions that only involve the first moment (the mean) such that problems of non-identifiability or parameter sloppiness can be relieved or even overcome. That way the efficiency and accuracy of distance based parameter inference strategies may be enhanced by higher order moment fitting. In comparison to [20], where the focus is on a comparison of probability density functions rather than on a comparison of statistical moments, model predictions based on the above mentioned ODE system are computationally much cheaper than those based on repeated realizations of the Gillespie algorithm. Analytic expressions for the steady state mean and variance of a scalar variable have been used in [35] in order to obtain initial guesses for a parameter inference routine based on comparing experimental histograms from stationary data with model predictions. Still, the latter are obtained as in [20] from repeated simulations of the (stationary) chemical master equation.

The moment fitting approach presented in our paper handles time series data and involves only the solution of a single moment ODE system rather than repeated stochastic simulations. This reduces the computational costs and allows one to build parameter sensitivities for gradient based optimization and solution analysis. In a sequence of illustrative examples with simulated data from the literature we demonstrate potential benefits of our approach and address future challenges.
\[ \frac{d\mu^2}{dt} = 2(q_1 - q_2)\mu^2(t) + (q_1 + q_2)\mu^1(t), \quad \mu^2(0) = 0 \]

for the mean \( \mu^1(\cdot; q) \) (the first moment) and the variance \( \mu^2(\cdot; q) \) (the second central moment) approximation of the discrete state variable \( x_i \), see Supporting Information S1 for a derivation. Due to the linearity of the rate function \( h \) with respect to \( x_i \), the very same system (1) is obtained if the true stochastic process is approximated by the diffusion approximation (12), (13) or by the linear noise approximation (22). Furthermore, \( \mu^1(\cdot; q) \) and \( \mu^2(\cdot; q) \) coincide with the true moments \( m^1(\cdot; q) \) and \( m^2(\cdot; q) \). Another consequence of the linearity of \( h \) is that (1) admits an analytical solution given by

\[
\mu^1(t; q) = \mu^1(0) e^{(q_1 - q_2)t}, \quad (2)
\]

\[
\mu^2(t; q) = \mu^1(0) \frac{q_1 + q_2}{q_1 - q_2} e^{(q_1 - q_2)t} (e^{(q_1 - q_2)t} - 1). \quad (3)
\]

For the purpose of data generation we have simulated the true stochastic process \( N = 1000 \) times by means of the Gillespie algorithm [4]. Figure 1 B shows 3 (out of 1000) realizations as example, Figures 1 C and D display the sample mean \( \tilde{\mu}^1 \) and the sample variance \( \tilde{\mu}^2 \) at the process observation times \( t_j \) derived from the data.

In order to infer the rate parameters \( q_1 \) and \( q_2 \) we first utilized the cost (or distance) function

\[ d^1(q) = \sum_{j=1}^{n_c} (\tilde{\mu}^1_j - \mu^1(t_j; q))^2 \]

for a comparison of the sample mean with the analytic mean expression (2). Choosing the initial parameter guess \( q^0 = [1,1]_T \) and the MATLAB [42] trust region optimization algorithm with default setting we obtained the parameter solution \( q^* = [1.2392, 2.2487]_T \) after 10 iteration steps. Though the mean concentration data are perfectly fit by \( \mu^1(t; q^*), \) see Figure 2 A, the solution \( q^* \) strongly deviates from the true parameter values \( q^t = [3,4]_T \). If \( \mu^2(t; q^t) \) is used to predict the sample variance, large errors can also be observed in the data space, see Figure 2 B.

The problem of non-identifiability is overcome if not only the first moment but also the second central moment is fitted to the available data, e.g., by minimizing the cost function

\[ d^2(q) = \sum_{j=1}^{n_c} (\tilde{\mu}^1_j - \mu^1(t_j; q))^2 + 0.1 \sum_{j=1}^{n_c} (\tilde{\mu}^2_j - \mu^2(t_j; q))^2. \quad (5) \]

Again starting from \( q^0 = [1,1]_T \) the minimization of \( d^2(q) \) after 13 iteration steps led to the parameter estimate \( q^* = [2.9492, 3.9415]_T \) which is nearly identical to the true solution \( q^t \). Figures 2 C and D indicate the quality of the data fit by the analytic moment expressions \( \mu^1(t; q^*) \) and \( \mu^2(t; q^*) \).

![Figure 1. Simulation and data of the linear birth death process.](image-url)

(A) A single realization of the true stochastic process with \( x_0 = 50 \) and rate parameters \( q_1 = 3, q_2 = 4 \). (B) Three (out of \( N = 1000 \)) realizations of the true stochastic process. The process is finished as soon as the case \( x = 0 \) occurs. (C) Sample mean \( \tilde{\mu}^1 \) at the discrete observation times \( t_j \). (D) Sample variance \( \tilde{\mu}^2 \) at the discrete observation times \( t_j \).

doi:10.1371/journal.pone.0043001.g001
As a consequence, the variance data cannot be explained by the second order moment expression once more yields a perfect match between the mean data and $m_{qq}^2$ which compares ignorance of the sample variance acceptable marginal posterior density distributions due to the as priors for the parameters, the algorithm failed to yield acceptable marginal posterior density distributions due to the ignorance of the sample variance $\mu^{2,2}$, see Figure 3 for details.

Results for Dimerisation Kinetics

Based on the Fokker Planck equation (13) of the diffusion modelling approach

$$\frac{\partial}{\partial t} \phi(x,t) = - \frac{\partial}{\partial x} \left\{ \left( -q_1 x (x-1) + q_2 (x_0 - x) \right) \phi(x,t) \right\}$$

$$+ \frac{1}{2} \frac{\partial^2}{\partial x^2} \left\{ \left( 2q_1 x (x-1) + 2q_2 (x_0 - x) \right) \phi(x,t) \right\}$$

the normal moment closure technique yields the nonlinear ODE system

$$\frac{\partial}{\partial t} \mu^1(t) = q_1 \mu^1(t)(1 - \mu^1(t)) + q_2 (x_0 - \mu^1(t)) - q_1 \mu^{2,2}(t),$$

$$\mu^1(0) = x_0$$

$$\frac{\partial}{\partial t} \mu^{2,2}(t) = -2q_1 (2\mu^1(t) + 2\mu^{2,2}(t)) - 2q_2 \mu^{2,2}(t)$$

$$+ 2q_1 \mu^1(t) (\mu^1(t) - 1) + 2q_2 (x_0 - \mu^1(t)), \mu^{2,2}(0) = 0$$

for the (approximative) mean $\mu^1(t, q)$ and the (approximative) variance $\mu^{2,2}(t, q)$ of the continuous state variable $x(t)$, see Supporting Information S1 for the derivation. The true stochastic process was simulated $N=1000$ times by means of the Gillespie algorithm [4] with initial molecule number $x_0=301$ and rate parameters $q^*=[0.005,0.03]^T$.

We first only focused on the sample mean data $\hat{\mu}^1$ and minimized the least squares objective function

$$d^1(q) = \sum_{j=1}^{n_t} (\hat{\mu}^1_j - \mu^1(t; q))^2$$

**Figure 2. Moment fitting for the linear birth death process.** (A) The minimization of the cost function (4) yields a perfect match between the mean data and the first moment expression $\mu^1(t, \tilde{q})$, but a parameter result $\tilde{q}=[1.2392,2.2487]^T$ with large deviations from the true values $q^*=[3,4]^T$. (B) As a consequence, the variance data cannot be explained by the second order moment expression $\mu^{2,2}(t, \tilde{q})$. (C) The alternative minimization of (5) once more yields a perfect match between the mean data and $\mu^1(t, \tilde{q})$ but in addition the significantly improved parameter estimate $\tilde{q}=[2.9492,3.9415]^T$. (D) As the fitting of the central second order moment has been explicitly taken into account by (5), now also the variance data is reproduced by $\mu^{2,2}(t, \tilde{q})$. doi:10.1371/journal.pone.0043001.g002
by means of the MATLAB [42] trust region routine. The initial parameter guess chosen was \( q^0 = [0.0047, 0.0177]^T \), for any \( q \) the model predictions \( \mu^j(t; q), j = 1, \ldots, n_j \), were obtained by solving the above mentioned ODE system, and the gradient of \( d^2(q) \) was provided by means of the adjoint method, see Supporting Information S2. Figures 4 A,C,E show that convergence of the iterates towards \( \hat{q} = [0.005, 0.0294]^T \) is obtained after 180 iteration steps. Though the mean data in this example is sufficient to obtain reliable parameter estimates (also for more distant initial guesses), a significant computational speed up is gained if not only the mean data but also the variance data \( \sigma^2 \) is taken into account. Figures 4 B,D,F display the performance of the same optimization algorithm with identical initial guess if applied to the minimization of the alternative objective function

\[
d^2(q) = \sum_{j=1}^{n_j} \left( \mu^j \sigma^2(t; q) \right)^2 + 0.1 \sum_{j=1}^{n_j} \left( \mu^j \sigma^2(t; q) \right)^2. \quad (8)
\]

The accuracy of the parameter estimate \( \hat{q} \) obtained with (8) is the same as of \( \hat{q} \) obtained with (7), however, convergence is now already achieved after 55 iterations. The outcome \( d^2(\hat{q}) > d^2(\hat{q}) \) is solely due to the additional variance term in (8) and does not allow for a comparative judgement of the inferred parameters.

Results for p53 Signalling System

The linear noise approximation [14] yields a nonlinear ODE system describing the temporal development of the mean approximation \( \mu^j(t; q) \in \mathbb{R}^2 \) and the covariance matrix approximation \( \mu^2(t; q) \in \mathbb{R}^{3 \times 3} \). For data generation, the true stochastic process was simulated \( N = 1000 \) times by means of the Gillespie algorithm [4] with the initial molecule numbers \( x_0 = [10, 10, 80]^T \) and the rate parameter vector \( q = [90, 0.002, 1.7, 1.1, 1.0, 8.2]^T \). First, we supposed that the two components \( x_1 \) and \( x_2 \) of the state vector \( x \in \mathbb{R}^3_+ \) can be observed. The minimization of the objective function

\[
d^1(q) = \sum_{j=1}^{n_j} (\hat{\mu}_1^j - \mu(t; q))^2 + \sum_{j=1}^{n_j} (\hat{\mu}_2^j - \mu(t; q))^2 \quad (9)
\]

with the initial guess \( q^0 = (1 + 0.1 \cdot (-1)^j) \cdot q^*, j = 1, \ldots, 7 \), showed that the corresponding sample mean data \( \hat{\mu}_1^j \) and \( \hat{\mu}_2^j \) are not sufficient to identify the true vector \( q^* \). Though the parameter estimate \( \hat{q} \) obtained after 120 iterations is able to reproduce the data, see Figures 5 A and B, it features a maximal relative error of 156\% in its second component, see Figures 6 A and B for details. For comparison, we next supposed that only the component \( x_1 \) is amenable to observations but both the corresponding mean estimate \( \hat{\mu}_1^j \) and the variance estimate \( \hat{\mu}_2^j \) from the data, see Figures 5 A and C. The minimization of the objective function

Figure 3. MCMC Metropolis random walk for the linear birth death process. Figures (A)-(F) show the output of a MCMC Metropolis random walk for the inference of the marginal parameter posterior density distributions using the likelihood function (6). The prior parameter distributions were chosen as \( q_1 \sim \Gamma(3.1) \) and \( q_2 \sim \Gamma(3.1) \), and the candidate parameter vector \( q' \) at stage \( j \) was given by \( q' = q^{(j-1)} + q^0 \) with random innovations \( q^0 \) drawn from \( U(-0.5, 0.5) \). The iteration number of the sampler was set to 100000 and the first 1000 steps were discarded as burn-in and ignored in the monitoring plots (A)-(F). (A,B) Trace plots of the marginal posterior distributions for \( q_1 \) and \( q_2 \) data but also the variance data. Though the mean data in this example is sufficient to obtain accurate parameter estimates (also for more distant initial guesses), a significant computational speed up is gained if not only the mean data but also the variance data \( \sigma^2 \) is taken into account. Figures 4 B,D,F display the performance of the same optimization algorithm with identical initial guess if applied to the minimization of the alternative objective function.
Figure 4. Iterative minimization for inference of the dimerisation process parameters. Iterative minimization of the cost functions (7) and (8) using the MATLAB trust region algorithm with default settings and and initial guess \( q^0 = [0.0047, 0.0177]^T \). The gradient information both for (7) and (8) was provided by means of the adjoint method in order to avoid error-prone finite differencing. (A) Plot of the value of the cost function (7) at the relative errors 

\[
\text{error of } q_i^0 \% \text{ in } \frac{d}{\text{iter} j} \text{ iteration index } j
\]

(B) Using the cost function (8) instead of (7), the algorithm already terminates after 55 (outer) iteration steps and yields the minimizer \( \tilde{q} = [0.005, 0.0294]^T \). (C) Plot of the relative errors \( 100 \times \| q_i^0 - q_i \|/\|q_i\| \), \( i = 1,2 \) show that convergence to the true parameter vector \( q^* \) is obtained (up to a negligible error in \( q_2 \)) if (7) is chosen as objective function. (D,E,F) Parameter convergence is also obtained if (8) is chosen instead of (7). However, parameter convergence is much faster in this case.

doi:10.1371/journal.pone.0043001.g004

The results of the analysis of the Hessian are also reflected in Figure 7 which plots the level sets of (4). The cost function is minimal on a whole line, whose direction is given by the two (normalized) eigenvectors are

\[
\{ \tilde{q}_1, \tilde{q}_2 \} = \{-1, 1\} \text{ and } 2(\tilde{q}_1)^2 = 2(\tilde{q}_2)^2 \text{ along the direction of maximal curvature (or the stiff direction). A large}\]

positive and far away from \( q^* \). With respect to the cost function (4) we have 

\[
d^T(q) = \frac{1}{2} \sum_{i,j} (\mu_{ij}^2 - \mu_i^2 \mu_j^2 - \mu_{ij}^2) + 0.01 \sum_{i,j} (\mu_{ij}^2 - \mu_i^2 \mu_j^2) \quad (10)
\]

(with the same initial guess and MATLAB trust region algorithm as for (9), gradient information again provided by the adjoint method) led - after only 33 iterations - to an improved parameter estimate \( \hat{q} \) whose maximal relative error (again in the second component) was reduced to 22.44%, see Figures 6 C and D for details.

Discussion

Our numerical tests by means of reference models from the literature show that comparing sample moments with theoretical moments may enhance parameter identifiability and the performance of parameter identification algorithms in comparison to mean-only approaches. These observations can be explained by an examination of the cost functions that have been used for the parameter inference. In the linear birth death example the mean expression (2) shows that any parameter combination \( (\tilde{q}_1, \tilde{q}_2)^T \) with \( \tilde{q}_1 = \tilde{q}_2 = -1 \) equally well explains the sample mean data as the true parameter vector \( q^* = (3, 4)^T \). The failure of the MCMC approach based on the likelihood (6) can be understood from plotting the negative log-likelihood along the line \( \tilde{q}_2 = \tilde{q}_1 + 1 \) which assumes its minimum at the boundary imposed by parameter
Figure 5. Moment fitting for the \( p53 \) model. (A, B) The minimization of the cost function (9) yields a perfect match between the sample mean data \( \mu_1^1, \mu_1^2 \) and the outputs \( \bar{\mu}_1^1(: \bar{q}), \bar{\mu}_1^2(: \bar{q}) \) (red curves) of the linear noise approximation for the \( d^1 \)-minimizer \( \bar{q} \). (C) The plot shows the variance data \( \mu_1^{c1} \) and the model output \( \bar{\mu}_1^{c1}(:: \bar{q}) \) (green curve) calculated with the minimizer \( \bar{q} \) of the cost function (10). Though the approximation errors are more pronounced the consideration of \( \mu_1^{c1} \) in the inference task yields a improved parameter estimate \( \bar{q} \).

doi:10.1371/journal.pone.0043001.g005

Figure 6. Iterative minimization for inference of the \( p53 \) model parameters. Iterative minimization of the cost functions (9) and (10) using the MATLAB trust region algorithm with default settings, the initial guess \( \bar{q}^{(0)} = (1 + 0.1 (i - 1)) q^*_i, \ i = 1, \ldots, 7 \), and the adjoint method for providing the gradient information. (A) Plot of the value of the cost function at the iterate \( q^{(j)} \). The optimization algorithm terminates after 120 (outer) iteration steps and yields the minimizer \( \bar{q} \). (B) Plot of the relative errors of \( \bar{q} \) in % showing a huge deviation from the true parameter \( q^*_i \) in the second and fourth components. (C) Plot of the value of the cost function at the iterate \( q^{(j)} \). The optimization algorithm terminates after only 33 (outer) iteration steps and yields the minimizer \( \bar{q} \). (D) The quality of the parameter estimate \( \bar{q} \) has significantly improved in comparison to \( \bar{q} \).

doi:10.1371/journal.pone.0043001.g006
explains the observation made in Figure 3. (C) Values of the cost function parameter solution, i.e., neighbourhood of the true solution as opposed to eigenvalues. A plot of the level sets, see Figure 7 D, indicates that – as before, the Hessian now is regular with a narrow span of the matrix, also reflected in the contour plots of the level sets, along the elongated and flat valley of \( d^3 \) before they reach the unique minimizer. In comparison, the level sets of the alternative cost function \([8]\) show a considerably smaller ratio between the major and minor axes of the ellipses, see Figure 6 B, such that the iterates may faster approach the minimizer. The condition number of the Hessian matrix \( H^1(q^*) \) for \( d^1 \) is given by \( \kappa_1(q^*) = \lambda_{\max}(q^*)/\lambda_{\min}(q^*) = 1911.3 \), while for the Hessian \( H^2(q^*) \) for \( d^2 \) a reduction by 25% is achieved. The observed algorithmic improvement is in agreement with gradient based optimization theory [13] according to which the rate of convergence improves if the condition number of the Hessian matrix, also reflected in the contour plots of the level sets, decreases.

Figure 7. Distance functions for the linear birth death process. The problem of minimizing the least squares error between the sample mean and the analytic mean \( \mu^1(q) \) has infinitely many global solutions \( q(s) = [0,1]^T + s [1,1]^T \) with \( s \in \mathbb{R}_+^2 \); (A) Values of the cost function \( d^1(q(s)) \) from (4) for \( s \in [0,6] \). (B) Values of the negative log-likelihood function \(- \log (L(q(s)))\) for \( s \in [0,6] \) with \( L(q) \) as in (6). The likelihood \( L(q(s)) \) is maximal for \( s = 0 \) which explains the observation made in Figure 3. (C) Values of the cost function \( d^2(q(s)) \) from (5) for \( s \in [0,6] \). The function also measures the distance between the second order sample and analytic moments and as a consequence we build a unique global minimum at \( s = 3 \) corresponding to the true parameter solution, i.e., \( q(3) = [3.4]^T = q^* \). In this example, \( s = 3 \) and \( d^1(q(s)) \neq 0 \) are due to the finite sampling number \( N \). (D) Level sets of the cost function \( d^1 \) indicate extreme parameter sloppiness and infinitely many parameter solutions. (E) Ellipsoidal level sets of the cost function \( d^2 \) in the neighbourhood of the true solution \( q^* \) indicate its unique identifiability.

doi:10.1371/journal.pone.0043001.g007

\[
H^2_{ij}(q) = \frac{\partial^2 \ell(q)}{\partial q_i \partial q_j}, \quad i,j \in \{1,2\}
\]

of (5) evaluated at \( q^* \) yields the eigenvectors \( v_1(q^*) = [-0.749, 0.663]^T \) and \( v_2(q^*) = [-0.663, -0.749]^T \) with corresponding eigenvalues \( \lambda_1(q^*) = 1.44 \times 10^5 \) and \( \lambda_2(q^*) = 306.14 \). Though the directions of largest and smallest curvature are similar as before, the Hessian now is regular with a narrow span of the eigenvalues. A plot of the level sets, see Figure 7 D, indicates that - as opposed to \( d^1 \) - the function \( d^2 \) admits a landscape with a sharp trough in the neighborhood of the isolated minimizer. The unique parameter identifiability is also evident from the quadratic behaviour of the cost function \( d^2 \) along the line \( q = q_0 + 1 \) (with direction \( [-\sqrt{0.5}, -\sqrt{0.5}]^T \)), see Figure 7 C, with its global minimizer corresponding to \( q^* \). These results hold true if the weighting parameter \( w_2 \) in the definition of \( d^2 \) is changed from 0.1 to, e.g., 1 or 0.01.

For the dimerisation example the level sets of the cost function (7) are shown in Figure 8 A. In this example the mean sample data is sufficient to uniquely determine the model parameter vector \( q^* \), at least if a nearby initial guess is chosen. But even then the iterates of a gradient based optimizer may be forced to slowly wander

\[
H^k_{ij}(q) = \frac{\partial^2 \ell(q)}{\partial q_i \partial q_j \partial \log(q)}, \quad i,j \in \{1,2\}, \quad k = 1,2
\]
by differentiation with respect to \( \log(q) \) in order to take relative changes in parameter values into account \[27\]. A relative comparison of the two condition numbers \( k_1(q'/C^3) \) and \( k_2(q'/C^3) \) yields

\[
\frac{k_2(q') - k_1(q')}{k_1(q')} = -0.85
\]

which corresponds to a reduction of the eigenvalue ratio \( \lambda_{\text{max}}(q')/\lambda_{\text{min}}(q') \) by 85% when using \( d^2 \) instead of \( d^1 \). This improvement is even more pronounced if the derivatives in the Hessian are taken with respect to \( q \) and is also clearly reflected in Figure 6.

Based on accepted mathematical descriptions of stochastic reaction networks in well-mixed conditions we have introduced the concept of moment fitting for parameter inference from time series data of repeated measurements. In numerical tests for simple reference examples we observed that if the common comparison of sample mean data with the parameter-dependent mean expression derived from the model is augmented by consideration of higher moments such as covariance, improvements both with respect to parameter estimate accuracy and algorithmic efficiency are achieved.

Our approach offers opportunities for extension and further research. In case of larger models and real data, then also affected by external noise, measures against data instability and overfitting become necessary. The regularization theory of nonlinear inverse problems \[7\], \[44\] suggests the application of stopping rules for the iterative minimization of cost functions in dependence on the quality of the data. Stopping for overfitting avoidance is also recommended from the viewpoint of data mining \[35\], then also referred to as pruning. Pruning in order to obtain a simple description that still fits the data can also be realized by augmenting the cost function with sparsity enforcing \( \ell_p \)-priors or penalties, i.e.,

\[
d_{\text{reg}}(q) = d(q) + \lambda \sum |q_i|^p, \ 0 < p \leq 1,
\]

see \[45\], \[46\], \[47\]. In the context of parameter inference for biochemical reaction networks \( \ell_p \)-penalization has been previously used in \[48\], \[49\], \[50\]. As the eigenvalues of the Hessian of a cost function \( d \) also reflect the degree of ill-conditioning of the parameter inference problem, our examples show that even the pure consideration of higher moments may have a beneficial effect with respect to the amplification of measurement errors. Other possible expansions of the moment fitting approach include the consideration of more elaborate state observation operators, unknown initial conditions or reaction rate parameters that themselves are treated as stochastic quantities.

In our examples we used squared errors to build the distance functions. This not only allowed us to numerically demonstrate the advantages of moment fitting but also to give explanations of the results in terms of Hessian matrices which in the squared error case can be computed in a straightforward manner. Furthermore, the squared error approach enables the straightforward utilization of the adjoint method, see Materials and Methods, for providing gradient information to the optimizer. Still, as moments of different order may be correlated \[51\], distance functions based on generalized least squares \[52\] might be an alternative in more demanding situations which then would require to provide covariance estimates for the moments to be fitted. Another idea is to use cost functions that are motivated by \( f \)-divergences \[53\] for the comparison of probability distributions such as the Hellinger divergence or the Kullback-Leibler divergence. For instance, the KL-divergence for multivariate normal distributions would suggest the cost function

\[
\text{Figure 8. Level sets of the cost functions for the dimerisation process.} (A) The level sets of the cost function } d^1 \text{ reveal an elongated and flat valley in which the iterates of gradient based optimizers may only slowly converge towards the minimizer } q' \text{. (B) The level sets of the cost function } d^2 \text{ form ellipses with smaller ratio of major axis over minor axis and correspond to a more pronounced trough. As a consequence the iterates converge faster towards } q'.
\]
\[ d(q) = \frac{1}{2} \sum_{i=1}^{m} \left\{ \log \left( \frac{\| \hat{\mu}_i^2 \|}{\| \mu_i^2 \|} \right) + \text{trace} \left( \hat{\mu}_i^{-1} \cdot \mu_i^{-1} (t_j; q) \right) \right. \\
\left. + \left( \hat{\mu}_i - \mu_i (t_j; q) \right) \hat{\mu}_i^{-1} \left( \hat{\mu}_i - \mu_i (t_j; q) \right) \right\} \]

but then poses severe challenges with respect to an efficient computational realization.

The moment fitting approach presented in this paper rests upon the availability of sufficient data for the estimation of higher moments as only then more traditional mean-only approaches may be outperformed. This raises the question of selecting the sample size \( N \) in the design of the experiments. In order to go beyond heuristics it is the goal of our future research to combine error estimates of sample moments, e.g.,

\[
E[(\hat{\mu}^1 - m)^2] = \frac{m^r}{N},
\]
\[
E[(\hat{\mu}^2 - m^2)^2] = \frac{1}{N} \left( m^{r^2} - \frac{N-3}{N-1} (m^r)^2 \right).
\]

see [54], with error estimates for the theoretical moment approximations described by the ODE system (21), see [55], [56], [41], [37] for preliminary results. An integrative error analysis may then also guide the choice of the moment order \( k \) of truncation and the choice of the factors \( w_k \) in weighted cost functions.

**Materials and Methods**

**Modelling Strategies**

In well-mixed conditions a network of \( l \) coupled chemical reactions \( R_1, \ldots, R_l \) involving \( n \) chemical species \( X_1, \ldots, X_n \) can be characterized by the formalism [2]

\[ R_j: \ s_{-j}X_1 + \ldots + s_{-j}X_n \xrightarrow{q_j} s_{+j}X_1 + \ldots + s_{+j}X_n, \]

where the integers \( s_{-j} \) and \( s_{+j} \), \( i = 1, \ldots, n \) denote the numbers of molecules consumed and produced in a single step of reaction \( R_j \). If \( x \in \mathbb{R}^n \) represents the vector of species molecule numbers and \( s \in \mathbb{R}^{\text{species}} \) denote the components of the stoichiometric matrix \( S \in \mathbb{R}^{n \times l} \), then the state vector is updated according to \( x \rightarrow x + S q \) whenever reaction \( R_j \) fires. Each reaction \( R_j \) is associated with a rate law (or hazard function) \( h_j(x, q_j) \) and a stochastic rate constant \( q_j \).

Let \( \pi(x,t) \) denote the probability of being in state \( x \) at time \( t \) given the initial condition \( \pi(0) \). Then, the time evolution of \( \pi(x,t) \) is described by the Kolmogorov differential equation (or chemical Master equation)

\[
\frac{\partial \pi}{\partial t}(x,t) = \sum_{j=1}^{l} \left\{ \pi(x - S_j, t)h_j(x - S_j, q_j) - \pi(x, t)h_j(x, q_j) \right\}. \quad (11)
\]

With \( h(x, q) = (h_1(x, q_1), \ldots, h_l(x, q_l))^T \in \mathbb{R}^l \) the diffusion approximation to the true process is based on the chemical Langevin equation [3]

\[
d_x = S h(x, q)dt + \sqrt{S \text{diag}(h(x, q))} S dW, \quad (12)
\]

where \( d_x \) is the change in state \( x(t) \in \mathbb{R}^n \) in an infinitely small time interval \( dt \) and \( dW \) is the increment of a \( n \)-dimensional Wiener process. In the stochastic differential equation (12) the stochastic perturbations are modelled by a state and rate parameter dependent Gaussian noise and the associated probability density function \( p(x, t) \) is described by the Fokker-Planck equation

\[
\frac{\partial p}{\partial t}(x, t) = -\sum_{i=1}^{n} \frac{\partial}{\partial x_i} \left\{ S h_i(x, q_i) \right\} p(x, t) \]
\[
+ \frac{1}{2} \sum_{i,j=1}^{n} \frac{\partial^2}{\partial x_i \partial x_j} \left\{ S S^T h_i(x, q_i) S S^T \right\} p(x, t). \quad (13)
\]

An alternative approximative description of the stochastic process is given by the linear noise approximation [6] which is derived from a Taylor expansion of (11) in powers of \( 1/\sqrt{\Omega} \) where \( \Omega \) denotes the volume of the reactive system. This leads to a decomposition of the molecule concentration vector \( c(t) = x(t)/\Omega \in \mathbb{R}^n \) according to

\[
c(t) = \phi(t) + \frac{1}{\sqrt{\Omega}} \xi(t) \quad (14)
\]

into a deterministic part \( \phi \) that solves the macroscopic rate equation

\[
\frac{\partial \phi}{\partial t}(x, t) = S h(x, q) \quad (15)
\]

and a stochastic process \( \xi \) described by a linear diffusion equation

\[
d\xi = S \frac{\partial h}{\partial \phi}(\phi, q) \xi dt + S \sqrt{\text{diag}(h(\phi, q))} dW \]

with the increment \( dW \) of a \( l \)-dimensional Wiener process.

Finally, the deterministic modelling approach [1], [57] ignores (if the justifying assumptions are satisfied) random fluctuations due to the stochasticity of the reactions and describes the time course of the species concentration vector \( c(t) \) by the set of ordinary differential equations

\[
\frac{\partial c}{\partial t}(t) = S h(c, q) \quad (16)
\]

which corresponds to (15) with the setting \( \phi(t) = c(t) \).

**Moments of the Random State Variable**

Depending on the chosen modelling approach the state variable of a stochastic biochemical reaction network is described as a discrete or a continuous random quantity. In the discrete case associated to the Kolmogorov differential equation (11) the first order moments [58] of the \( n \)-dimensional state variable \( x(t) \) are given by
where $E$ is the expectation operator and $\mathcal{X}$ denotes the countable state space. Using this formalism the $n$-dimensional mean vector $m^1[x(t)]$ of $x(t)$ is described by

$$m^1[x(t)] = \left( \begin{array}{c} m_{1,0,\ldots,0}(x,t) \\ \vdots \\ m_{0^{\bar{n}},0,\ldots,0}(x,t) \end{array} \right) = \left( \begin{array}{c} E[x_1(t)] \\ \vdots \\ E[x_n(t)] \end{array} \right) = \left( \begin{array}{c} \sum_{x \in \mathcal{X}} \tilde{x}_1(t) \pi(\tilde{x},t) \\ \vdots \\ \sum_{x \in \mathcal{X}} \tilde{x}_n(t) \pi(\tilde{x},t) \end{array} \right).$$

In general, the $k$-th order moments $[58]$ are given by

$$m^k_{1,\ldots,r_n}(x,t) = E[\prod_{i=1}^n x_i^k(t)] = \sum_{\tilde{x} \in \mathcal{X}} \left( \prod_{i=1}^n \tilde{x}_i^k(t) \right) \pi(\tilde{x},t), \text{ with } r_1 + \cdots + r_n = k \quad (17)$$

and the $k$-th central moments $[58]$ are given by

$$m^{c,k}_{1,\ldots,r_n}(x,t) = E[\prod_{i=1}^n (x_i(t) - E[x_i(t)])^k] = \sum_{\tilde{x} \in \mathcal{X}} \left( \prod_{i=1}^n (\tilde{x}_i(t) - E[x_i(t)])^k \right) \pi(\tilde{x},t)$$

with $r_1 + \cdots + r_n = k$. For instance, the covariance matrix $m^{2,2}[x(t)] \in \mathbb{R}^{n \times n}$ of $x(t)$ is described by the 2nd order central moments according to

$$m^{2,2}[x(t)] = \begin{pmatrix} m_{2,0,\ldots,0}^{2}(x(t)) & m_{1,1,\ldots,0}^{2}(x(t)) & \cdots & m_{0,0,\ldots,0}^{2}(x(t)) \\ m_{1,1,\ldots,0}^{2}(x(t)) & m_{0,2,\ldots,0}^{2}(x(t)) & \cdots & m_{0,0,\ldots,1}^{2}(x(t)) \\ \vdots & \vdots & \ddots & \vdots \\ m_{0,0,\ldots,0}^{2}(x(t)) & m_{0,0,\ldots,1}^{2}(x(t)) & \cdots & m_{0,0,\ldots,2}^{2}(x(t)) \end{pmatrix}.$$

In case the state space of the biological system is modelled as a continuous random variable $x$ its moments are described the same way after switching from the summation over a probability mass function $\pi(x,t)$ to an integration over a probability density function $p(x,t)$ as e.g., defined by the Fokker Planck equation (13). For instance, the $k$-th order moments then are given by

$$m^k_{1,\ldots,r_n}(x,t) = E[\prod_{i=1}^n x_i^k(t)] = \int_{-\infty}^{\infty} \cdots \int_{-\infty}^{\infty} \left( \prod_{i=1}^n x_i^k(t) \right) p(x,t) dx_1 \cdots dx_n, \text{ with } r_1 + \cdots + r_n = k. \quad (18)$$

### Differential Equations for the Moments

Based on the differential equations (11) and (13) for the probability mass and density functions, differential equations that approximatively describe the time evolution of the $k$-th order moments (17) and (18) or their centered counterparts can be derived. For instance, the time evolution of the mean vector $m^1[x(t)] \in \mathbb{R}^n$ of the discrete state $x(t) \in \mathbb{N}_0^n$ is given by

$$\frac{\partial}{\partial t} m^1[x(t)] = \sum_{x \in \mathcal{X}} \frac{\partial}{\partial t} \tilde{x}_r(t) \pi(\tilde{x},t) = SE[h(x(t),q)], \quad (19)$$

see [2], [37]. Note that (19) corresponds only to the deterministic differential equations for their time evolution $[18]$ in case of a propensity function $h(x,q)$ that is linear in $x$ as

$$E[h(x(t),q)] = h(m^1[x(t)],q)$$

holds only then. Another example is the time evolution of the $k$-th order moments of a continuous state variable $g(t) \in \mathbb{R}$ which based on the Fokker Planck equation (13) for $n = 1$ is given by

$$\frac{\partial}{\partial t} m^k[g(t)] = \frac{\partial}{\partial \tilde{z}} \int_{-\infty}^{\infty} \tilde{z}^k p(\tilde{z},t) d\tilde{z}$$

$$= k \int_{-\infty}^{\infty} \tilde{z}^{k-1} S h(\tilde{z},q) p(\tilde{z},t) d\tilde{z} + \frac{k(k-1)}{2} \int_{-\infty}^{\infty} \tilde{z}^{k-2} S \text{diag}(h(\tilde{z},q)) S^T p(\tilde{z},t) d\tilde{z}$$

$$= k \frac{\partial}{\partial \tilde{z}} \int_{-\infty}^{\infty} \tilde{z}^{k-1} S h(\tilde{z},q) p(\tilde{z},t) d\tilde{z} + \frac{k(k-1)}{2} \int_{-\infty}^{\infty} \tilde{z}^{k-2} S \text{diag}(h(\tilde{z},q)) S^T p(\tilde{z},t) d\tilde{z}$$

$$= k E[g(t)^{k-1} S h(g(t),q)] + \frac{k(k-1)}{2} E[g(t)^{k-2} S \text{diag}(h(g(t),q)) S^T]. \quad (20)$$

The simple example $l = n = 1$ with $h(x,q) = qx^2$ in (20) yields.

$$k E[g(t)^{k-1} S h(g(t),q)] = k q E[g(t)^{k+1}] = k q m^{k+1}[g(t)]$$

and implies the dependency of the ordinary differential equation for $m^k[g(t)]$ on the higher moment $m^{k+1}[g(t)]$. This type of dependency is typical for the moments $m^k_{1,\ldots,r_n}[g(t)]$ or $m^k_{1,\ldots,r_n}[x(t)]$ whenever $h(x,q)$ is a nonlinear function of $x$ and may render the exact differential equations for their time evolution impossible to solve analytically or numerically. The problem may be overcome by the technique of moment closure [37], [38], [39], [40], [41] which sets moments or central moments above a certain order $k$ of interest equal to zero or alternatively replaces them by expressions depending only on moments up to order $k$. As a result one obtains (manually or supported by symbolic computation tools [39], [59]) a self-contained (or closed) set of coupled ordinary differential equations

$$\mu_{r_i}(t) = F(\mu(t),q), \quad (21)$$

Moment Fitting for Rate Parameter Inference
in which \( \mu(t) = (\mu_1(t), \mu_2(t), \ldots, \mu_k(t)) \) or \( \mu(t) = (\mu_1(t), \mu_2(t), \ldots, \mu_k(t)) \) approximately describes the time evolution of the true moments \( m(t) = \left( m_{1_1}^1(x_1(t), \ldots, x_n(t)), \ldots, m_{1_k}^k(x_1(t), \ldots, x_n(t)) \right) \) or \( m(t) = \left( m_{1_1}^1(x(t)), m_{1_k}^k(x(t)), \ldots, m_{1_k}^k(x(t)) \right) \). In our notation we emphasize the dependency of \( \mu \) on the rate parameters by writing the solution of (21) (to be supplemented by appropriate initial conditions) as \( \mu(t; q) \). The final form of (21) depends on the rate parameters \( m \).

As an alternative to the moment closure approach, a closed discretization of the time interval \( [0,t_f] \) with \( n_t = 85 \). In particular, we do not consider the times and types of the reactions that are fired during the realisation of the stochastic process as amenable to our observations.

**Dimerisation kinetics.** A simple reaction system featuring a nonlinear rate function is the dimerisation process [2], [39]. For the species \( P \) and \( P_2 \) with molecule numbers \( x_1 \) and \( x_2 \) we consider

\[ R_1 : X \xrightarrow{q_1} 2X \]

\[ R_2 : X \xrightarrow{q_2} \emptyset \]

with the associated stoichiometric matrix \( S \) and the rate functions \( h \) in terms of \( P \) only, i.e., with \( X = P \) and \( x = x_1 \in \mathbb{N}_0 \) we obtain

\[ S = \begin{pmatrix} 1 & -1 \end{pmatrix}, \quad h(x,q) = \begin{pmatrix} h_1(x,q_1) \\ h_2(x,q_2) \end{pmatrix} = \begin{pmatrix} q_1x \\ q_2x \end{pmatrix}. \]

In all simulations of the discrete stochastic dynamics of the model we chose the rate parameters \( q^* = (q_1^*, q_2^*)^T = (3,4)^T \) and the initial condition \( x_0 = 50 \).

With respect to the parameter inference problem we suppose that the state variable

\[ x = \{ x(t) \mid t \in [0,t_f] \} \in \mathcal{F}([0,t_f], \mathbb{N}_0) \]

allows to formulate the stoichiometric matrix \( S \) and the rate functions \( h \) for a one-dimensional state space. In all simulations of the discrete stochastic dynamics of the model we chose the rate parameters \( q^* = (q_1^*, q_2^*)^T = (0.005,0.03)^T \), the total molecule number \( x_0 = 301 \) and the initial condition \( x_0 = 50 \). With respect to the parameter inference problem we chose the same observation operator \( O \) as in (24), now with the setting \( t_f = 6.7 \) and \( n_t = 67 \).

**p53 Signalling System.** For testing the practicability of our approach in case of partial state observations we have chosen a model for the p53 signalling system which features a feedback loop between the tumor suppressor p53, the oncogene Mdm2 and its precursor pre-Mdm2. The model was introduced in [61] and also studied in [31]. With \( X = (p53, pre-Mdm2, Mdm2) \) and the associated vector \( x = (x_1, x_2, x_3)^T \in \mathbb{N}_0^3 \) of molecule copy numbers, its stoichiometric matrix \( S \) and rate functions \( h \) are given by

\[ t_{j+1} = t_j + (j+1) \frac{t_f}{n_t}, j = 0, \ldots, n_t - 1, \quad (23) \]
The corresponding observation operators are

\[
S = \begin{pmatrix}
1 & -1 & -1 & 0 & 0 \\
0 & 0 & 0 & 1 & -1 \\
0 & 0 & 0 & 0 & 1
\end{pmatrix},
\]

then yields the sequence

\[
h(x,q) = \begin{pmatrix}
h_1(x,q_1) \\
h_2(x,q_2) \\
h_3(x,q_3) \\
h_4(x,q_4) \\
h_5(x,q_5) \\
h_6(x,q_6)
\end{pmatrix} = \begin{pmatrix}
q_1 \\
q_2x_1 \\
q_3 + x_3 \\
q_4x_1 \\
q_5x_2 \\
q_6x_3
\end{pmatrix}
\]

In all simulations of the discrete stochastic dynamics of the model we chose the rate parameters \( q^* = \begin{pmatrix} q_1^*, q_2^*, q_3^*, q_4^*, q_5^*, q_6^* \end{pmatrix}^T = [0.0, 0.02, 1.7, 1.1, 1.0, 8.2]^T \) and the initial conditions \( x(0) = [10, 10, 80]^T \). With respect to the parameter inference problem we chose the time discretization as in the previous examples and supposed that either the component \( x_1 \) or both the components \( x_1 \) and \( x_2 \) are amenable to observations. The corresponding observation operators are

\[
O^1: \mathcal{F}(0,t_f] \otimes \mathbb{R}^{d \times n_t} \rightarrow \mathbb{R}^{1 \times n_t}, \quad x \rightarrow y = (x_1(t_1), \ldots, x_1(t_{n_t}))
\]

and

\[
O^2: \mathcal{F}(0,t_f] \otimes \mathbb{R}^{d \times n_t} \rightarrow \mathbb{R}^{2 \times n_t}, \quad x \rightarrow y = (x_1(t_1), \ldots, x_1(t_{n_t}), x_2(t_1), \ldots, x_2(t_{n_t})).
\]

The time observation parameters were chosen as \( t_f = 11.1 \) and \( n_t = 111 \).

**Data Generation and Sample Moments**

All molecular copy numbers used in our tests have been generated by MATLAB [42] simulations of the discrete stochastic model dynamics using the Gillespie algorithm [4]. In general, a single realization of the process allows to mimic a single observation of the system giving rise to an experimental concentration data matrix \( \tilde{y} \in \mathbb{R}^{d \times n_t} \). Here, \( n_t \) is the time discretization parameter and \( d \) is the number of observable components of the state variable as defined by the state observation operator

\[
O: \mathcal{F}(0,t_f] \otimes \mathbb{R}^{d \times n_t} \rightarrow \mathbb{R}^{d \times n_t}, \quad x \rightarrow y.
\]

A \( N \)-time repetition of the experimental observation of the system (or the computational realization of the stochastic process) then yields the sequence

\[
\tilde{y}^1, \ldots, \tilde{y}^N
\]

of data matrices. For each discrete time point \( t_j \) the data matrix \( \tilde{y}^j \) allows to calculate sample moments \([62],[63]\). For instance, the sample mean of the observables at time \( t_j \) is given by

\[
\bar{y}_j = \frac{1}{N} \sum_{i=1}^{N} y_j^i \in \mathbb{R}^d,
\]

while the empirical covariance matrix of the observables at time \( t_j \) is given by

\[
\sigma_j = \frac{1}{N-1} \sum_{i=1}^{N} (y_j^i - \bar{y}_j)(y_j^i - \bar{y}_j)^T \in \mathbb{R}^{d \times d},
\]

in which \( y_j^i, \bar{y}_j^i, \sigma_j^i \) denote the \( s \)-th components of the vectors \( y_j^i, \bar{y}_j^i, \sigma_j^i \). An alternative covariance matrix estimate that is more suitable if \( N \ll d \) is not satisfied is given in [64]. In general, the data tensor \( \bar{y} \in \mathbb{R}^{d \times d \times N} \) allows to compute the tuple

\[
\bar{y}^o = \left( \bar{y}_1^o, \ldots, \bar{y}_N^o \right)
\]

of length \( n_t \), where \( \bar{y}_j^o \) denotes the sample moments of the observable state components up to the order \( k \) at time \( t_j \). An example with \( k = 2 \) is

\[
\bar{y}^o = \left( \bar{y}_1^{2,0}, \bar{y}_2^{2,0}, \ldots, \bar{y}_N^{2,0} \right)
\]

with sample mean vector \( \bar{y}_j^{2,0} \) and sample covariance matrix \( \sigma_j^{2,0} \) at time \( t_j \).

**Cost Functions and Adjoint Method**

If we split the state variable \( x \in \mathbb{R}^{n_0} \) into the observable part \( x^o \in \mathbb{R}^{n_0-\alpha} \) and the unobservable part \( x^u \in \mathbb{R}^{\alpha} \) according to \( x = [x^o; x^u] \), this separation carries over to the \( k \)-th order moments of \( x \) approximatively described by the ODE system (21), i.e.,

\[
\bar{y}^o(\cdot; q) = \mu^o(\cdot; q); \sigma^o(\cdot; q). \]

This is to be understood in the sense that there exists a (linear) splitting operator \( \mathcal{N} \) with

\[
\bar{y}^o(\cdot; q) = \mathcal{N} \bar{y}(\cdot; q).
\]

Then, in order to compare the parameter dependent solution component \( \mu^o(\cdot; q) \) of the ODE system (21) with the available sample moment tuple \( \bar{y}^o \) various distance measures

\[
d(\bar{y}^o, \mathcal{D}\bar{y}^o(q))
\]

may be utilized where the time discretization operator \( \mathcal{D} \) simply evaluates the time-dependent \( \mu^o(\cdot; q) \) function at the discrete times \( t_j \) of (23), i.e.,
where, in general, choice \( w_k \) order moment comparison. As shown in the results section the estimate an ordering of the weights according to lower order statistical moments in general are easier to approximate parameter inference problem for stochastic biological models. As

\[ \mu^i(\cdot; q) = (\mu^1(\cdot; q), \mu^2(\cdot; q)) \]

Examples for \( k = 2 \) with \( \mu^i(\cdot; q) = (\mu^1(\cdot; q), \mu^2(\cdot; q)) \) include

\[
d(\hat{\mu}^i, DN(q)) = w_1 \sum_{j=1}^{n_y} \left[ \mu^{1,0}_j - \mu^{1,0}(t_j; q) \right]^2 + w_2 \sum_{j=1}^{n_y} \left[ \mu^{2,0}_j - \mu^{2,0}(t_j; q) \right]^2,
\]

\[
d(\hat{\mu}^i, DN(q)) = w_1 \sum_{j=1}^{n_y} \left[ \mu^{1,0}_j - \mu^{1,0}(t_j; q) \right]^2 + w_2 \sum_{j=1}^{n_y} \left[ \mu^{2,0}_j - \mu^{2,0}(t_j; q) \right]^2,
\]

where, in general, \( w_k \) denotes the weight associated to the \( k \)th order moment comparison. As shown in the results section the choice \( w_k \neq 0 \) for \( k > 1 \) can make a decisive difference in the parameter inference problem for stochastic biological models. As lower order statistical moments in general are easier to approximate an ordering of the weights according to \( w_k > w_{k+1} \) seems reasonable. In our tests we chose the weights by trial and error heuristics. Though we observed comparable performances for weights within a proper range, rules for the choice of \( w_k \) in dependence on \( k \) and the quality of data are desirable, see Discussion.

With respect to parameter inference the difference function (26) can be utilized in various manners. For instance, it can be minimized by deterministic or stochastic optimization routines, it can be incorporated as a cost function in approximate Bayesian methods or used in building Kalman filters or Luenberger type observers. In the context of gradient based optimization, the gradient information can be efficiently provided by means of the so-called adjoint technique whenever \( d \) can be written as a parameter dependent \( \langle \cdot, \cdot \rangle_q \) or parameter independent \( \langle \cdot, \cdot \rangle \) inner product of the residual \( r(q) = \hat{\mu}^i - DN(q) \) with itself, see Supporting Information S2.
