Abstract

Iron overload has been associated with carcinogenesis in humans. Intraperitoneal administration of ferric nitrilotriacetate initiates a Fenton reaction in renal proximal tubules of rodents that ultimately leads to a high incidence of renal cell carcinoma (RCC) after repeated treatments. We performed high-resolution microarray comparative genomic hybridization to identify characteristics in the genomic profiles of this oxidative stress-induced rat RCCs. The results revealed extensive large-scale genomic alterations with a preference for deletions. Deletions and amplifications were numerous and sometimes fragmented, demonstrating that a Fenton reaction is a cause of such genomic alterations in vivo. Frequency plotting indicated that two of the most commonly altered loci corresponded to a Cdkn2a/2b deletion and a Met amplification. Tumor sizes were proportionally associated with Met expression and/or amplification, and clustering analysis confirmed our results. Furthermore, we developed a procedure to compare whole genomic patterns of the copy number alterations among different species based on chromosomal syntenic relationship. Patterns of the rat RCCs showed the strongest similarity to the human RCCs among five types of human cancers, followed by human malignant mesothelioma, an iron overload-associated cancer. Therefore, an iron-dependent Fenton chemical reaction causes large-scale genomic alterations during carcinogenesis, which may result in distinct genomic profiles. Based on the characteristics of extensive genome alterations in human cancer, our results suggest that this chemical reaction may play a major role during human carcinogenesis.

Introduction

Cancer is a disease of accumulated genomic alterations, presumably caused by a systematic process during cellular injury and repair. Causative agents for carcinogenesis are numerous including γ-radiation, ultraviolet radiation, inflammation, chemicals and iron overload [1]. Genomic data of a variety of human cancers is currently analyzed either with array-based comparative genomic hybridization (CGH) [2] or next-generation sequencing [3,4]. These projects are performed to find causative gene mutations that will lead to identifying novel chemicals or antibodies directed for the interactions of responsible signaling molecules. These efforts are expected to result in developments of effective drugs. However, cancer prevention in daily life is as important as its therapy. In the present study, we sought to resolve roles of iron-mediated oxidative stress during carcinogenesis using array-based CGH. Oxidative stress is constitutively caused by the metabolism of molecular oxygen [5], but is mainly regulated by various antioxidant systems. However, in a variety of pathological conditions, oxidative stress loads exceed the antioxidant capacity [6]. Iron is the most abundant heavy metal in mammals, such as rodents and humans. Whereas iron is essential for oxygen transport as a component of hemoglobin, excess iron has been associated with carcinogenesis [7,8], presumably through a Fenton reaction [9]. Ionic forms of iron are barely soluble at a neutral pH, but ferric nitrilotriacetate (Fe-NTA), an iron chelate, is soluble at pH 7.4 and is an efficient catalytic agent for the Fenton reaction [10]. In the 1980s, our group established that repeated intraperitoneal administrations of Fe-NTA induce a high incidence of renal cell carcinoma (RCC) in rodents [11,12]. Later, we...
showed that the renal injury occurs through a Fenton reaction with a variety of hydroxyl radical-mediated chemical products, such as 8-hydroxy-2'-deoxyguanosine [13,14] and 4-hydroxy-2-nonenal [15,16]. It is established that an iron overload in many pathological conditions is associated with the presence of catalytic iron [17,18]. Accordingly, by evaluating whole genome of RCCs, we could find a general principle for the genomic alterations under oxidatively-stressed conditions. We reported a Cdkn2a/2b deletion using microsatellite analysis in this model [19]. In this study, we evaluated the whole genome of Fe-NTA-induced rat RCCs and their cell lines using array-based CGHs. Furthermore, we transformed the data into a human genome through chromosomal syntenic relationship and analyzed the association.

Results

Genome-wide Views of DNA Copy Number Alterations in Fe-NTA-induced Rat RCCs

Fifteen rat RCC DNA samples, which included 13 primary tumor samples and 2 cell line samples, were hybridized on Agilent oligonucleotide microarrays for CGH with 181,978 genomic loci (GEO accession: GSE36101). Comparing different array-based CGH profiles in a quantitative manner is difficult. A shift in the mean copy number is caused by polyploidy and the contamination of normal cells. Therefore, we have developed a statistical method that considers these factors to estimate the chromosomal copy number [Methods S1]. In this paper, array-based CGH profile data analyses are based on the estimated copy numbers using this method.

Array-based CGH profiling revealed that genomes of the Fe-NTA-induced rat RCCs are often complex and have many extensive chromosomal alterations (Figs. 1A and S1). A whole genome frequency analysis with 15 samples identified recurrent regions of a copy number aberration in the Fe-NTA-induced RCCs (Fig. 1B). Copy number aberrations were determined based on the distribution of the log2 ratio values that were recalculated with the estimated copy number for a set of 13 primary tumors and 2 cell lines (Fig. S2). In this distribution, the thresholds that represented gain and loss were chosen at ±0.377. A threshold representing amplification was chosen at +0.811 whereas a homozygous deletion (complete loss) was assigned to the position at which the copy number was estimated as 0. The most characteristic global feature uncovered by the frequency analysis was a predisposition to lose an extensively wide region of chromosomes, especially for chromosomes 3, 5, 6, 8, 9, 14, 15, 17 and 20. The second feature was a frequent amplification over a long pericentromeric region in chromosome 4.

Frequent Chromosomal Loss in Rat Chromosome 5 and Homozygous Deletion at the Cdkn2a/2b Locus

Chromosome 5 underwent an extensive loss in copy number, not less than that in other chromosomes (e.g., chromosomes 6, 8 and 20) (Fig. 1B). As it relates to extensive loss, homozygous deletions were most frequently observed at the Cdkn2a/2b locus on chromosome 5 (Fig. 2A). This commonly deleted region included two loci (Cdkn2a and Cdkn2b) for three distinct tumor suppressor genes (p16 and p19 in Cdkn2a and p15 in Cdkn2b) (Fig. 2B). Shutdown of p16/p19 and p15 mRNA expression was confirmed in the samples that contained a homozygous deletion at the Cdkn2a/2b locus (Figs. 2C and 2D). In samples with a hemizygous deletion at the Cdkn2a locus (i.e., FB32-4, FB28-7), p16 and p19 expressions were downregulated, presumably because the promoter regions of the remaining alleles were methylated. However, some of the samples with either a hemizygous or no deletion (e.g., FB14-3; BF31-1; FB14-6; FB30-5 and FB33-7) showed a marked overexpression of p16 and p19.

Frequent Amplifications Over the Pericentromeric Region of Chromosome 4 and Amplification at the Met Locus

Over a long portion of the pericentromeric region in chromosome 4, frequent copy number gain and amplification were observed (Fig. 1B). Genomic amplification and gene expression in the corresponding areas of chromosome 4 were mostly proportional (Fig. S3). A bar plot of the amplified region along the pericentromeric region in chromosome 4 revealed that Met oncogene resides in the most common overlapping genomic section (Fig. 3A). The most overlapping section with a length of approximately 222 kb consisted of an amplified region in 11/15 samples and contained only one RefSeq-curated gene (Met) (Fig. 3B). A greater than 5-fold increase in Met mRNA expression was observed in 6 samples among the 9 tumors that contained a genomic amplification of Met (Fig. 3C).

Collectively, regarding chromosomal aberrations at these two cancer-related loci, every examined carcinoma including the two cell lines contained either the Met amplification or the Cdkn2a/2b deletion (Table 1, Figs. 2B and 3B). Other common genetic alterations are summarized in Table S1 (20 deleted genes, common in 2–4 RCC tumors) and Table S2 (340 amplified genes, common in 2–9 RCC tumors). Among those Zeb2/3B amplification was confirmed for overexpression (Fig. S4).

Tumor Size of Fe-NTA-induced RCCs is Regulated by Genetic Features

We examined the associations between genetic alterations and various RCC traits including those summarized in Table 1. Among all of the relationships examined, Met expression and tumor size were proportionally associated (Fig. 4A). Furthermore, a hierarchical clustering of tumors based on whole patterns of chromosomal changes revealed that a group of large tumors (i.e., FB7-7, FB30-5 and FB33-7) corresponded to a distinct cluster (Fig. 4B). Therefore, a tumor trait, size at the time the tumor was clinically overt, was associated with the entire array-based CGH profiles.

Comparison of Copy Number Alteration Profiles in Cancer Genomes Between Rats and Humans

To determine the general principle of large-scale genomic changes in cancer across mammalian species, we compared cancer genomes of rats and humans as a whole spectrum of chromosomal alterations. First, we transformed the rat array-based CGH profiles onto human chromosomes according to a synteny between the two species. Thereafter, we compared the whole patterns based on estimated copy numbers using multidimensional data analysis methods. We found that Fe-NTA-induced rat RCC was most similar to human RCCs, followed by human malignant mesothelioma (Fig. 5A and 5B).

Discussion

In this study, we report for the first time analyses of the entire data from array-based CGH applied to a Fenton chemistry-induced carcinogenesis in a rat kidney model [20]. We found that oxidative stress causes extensive genomic alterations in the induced cancer genome at chromosomal level (Fig. 1A). It is well known that a majority of human malignant solid tumors possess gains or losses in numerous chromosomes [21,22], and amplification can
be a suitable target for cancer chemotherapy. During the carcinogenic process of such tumors, chromosomal instability is thought to contribute as a driving factor [23]. Among wild-type rodent carcinogenesis models, however, few models report using primary tumor samples extensive genetic alterations because of chromosomal instability [24,25]. Radiation-induced murine malignant lymphoma [26] and murine lung adenocarcinoma induced by 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone, a carcinogen present in tobacco smoke [27], revealed slightly more gross chromosomal aberrations than the corresponding spontaneous tumors, albeit the low resolution in the report (bacterial artificial chromosome [BAC] array of 6,500). The facts that control rats exhibit no RCCs [11,12] and Fe-NTA-induced rat RCC model exhibits an equivalence to human cancers in genomic alterations at chromosomal level strongly support the idea that this carcinogenesis model mimics an actual carcinogenic process in those humans who lack strong cancer susceptibility traits.

Conversely, mice with multiple genetically-engineered cancer-associated genes show genetic alteration of this kind [28]. We think that those experiments correspond to an established mutator phenotype [29] and, thus, to the carcinogenic process in humans who have strong cancer susceptibility traits such as Li-Fraumeni syndrome (p53) [30] or melanoma kindreds (p16) [31]. As a hereditary rat RCC model, we also analyzed the RCCs of Eker rats, which do not show aggressive characteristics, such as metastasis [32,33,34]. We observed that these RCCs showed null

or subtle genetic alterations (Fig. S5). Accordingly, oxidative stress, including that induced due to excess iron, could be one of the causes of human renal carcinogenesis. Indeed, numerous epidemiological studies have associated iron and steel industry workers with an increased RCC risk [35].

A frequency plot analysis revealed two remarkable features. First, the chromosomal aberrations showed a preference for loss against the ploidy of each cancer genome. Mostly, the aberration was represented by a deletion at either a whole chromosomal level (monosomy) or at a segmental level (Fig. 1B). The most common target for loss was the Cdkn2a/b locus. The predominance of loss in the profile of chromosomal alterations may be attributed to the early stage of carcinogenesis. We previously demonstrated that cells with a hemizygous deletion at Cdkn2a appear as early as a few weeks after initiating a Fe-NTA administration [36].

Our present analysis revealed that the monoallelic loss of chromosome 5 in its entirety or of an equivalently wide region is the major first event. Indeed, we found only one case (6.7%) of a monoallelic loss of an extremely narrow region (~350 kilobases; Figs. 2A and 2B). Fe-NTA catalyzes the generation of hydroxyl radicals through a Fenton reaction specifically in the lumina of renal proximal tubules, which leads to degeneration and necrosis/apoptosis of those cells [37,38]. Because kidney is a vital organ that performs urea excretion, reabsorption of valuable molecules as

doi:10.1371/journal.pone.0043403.t001

Figure 4. Tumor sizes of Fe-NTA induced RCCs are controlled by the genetic features. (A) Met expression is significantly correlated with tumor size. Pearson’s correlation coefficient (r) and the corresponding P value are written on the plot area. (B) Hierarchical clustering of the RCC tumors based on the whole genome patterns of the copy number changes. The large-size tumors form a distinct cluster.
doi:10.1371/journal.pone.0043403.g004
well as ionic homeostasis maintenance, regeneration from the
remaining tubular cells is intensely promoted. Under chronic
oxidative stress by repeated Fe-NTA administrations, this de-
generation and regeneration process would continue for months to
years, increasing the risk of mitotic events simultaneously with the
repair of oxidative DNA damage. We believe that this oxidative
stress causes abnormal DNA replication and chromosomal
misseggregation, which leads to the emergence of aneuploid cells.
Surprisingly, this series of events appear to occur in months,
leading to a high incidence (90%) of RCC in rats within two
years. Aneuploid cells usually exhibit phenotypes consistent with
increased energy need and proteotoxic stress. However, aneuploi-
dy can promote tumorigenesis under the following two hypothet-
ical mechanisms: 1) aneuploidy may cause a proliferative advan-
tage through loss of G1/S transition control under conditions in
which normal euploid cells do not divide [39] and 2) aneuploidy
can advance tumorigenesis by promoting genomic instability,
thus increasing the evolvability of tumors [40]. The frequent
deletion of the Clda2a/2b locus is observed in the rat peritoneal
mesothelioma, an iron overload-associated tumor [41], induced
either by another iron compound (ferric saccharate) [42] or by
asbestos [43]. These common traits of animal models strongly
suggest that Clda2a/2b is a principal target in iron-mediated
carcinogenesis. The same genetic alteration is observed in rat
mesothelioma induced by multi-walled carbon nanotubes [44], in
which iron involvement is not yet established. We would like to
add here for the biological significance of our results that
homoygous deletion of Cdkn2a/2b is frequently observed in
human mesothelioma associated with asbestos exposure [45,46].

Some of the tumors with a remaining Clda2a/2b allele showed
extremely high expression levels of two products from this locus,
p16/Ink4a and p19Arf. This is a currently debated issue in human
cancer [47]. There is considerable evidence that several neoplasms
exhibit significant p16 levels in cytoplasm [48]. This can be an
unsuccessful attempt to stop cell proliferation in the case of
downstream Rb dysregulation [49] or may represent an alternative
mechanism for modulating unidentified pathways. Our data
exhibit ~50% hemizygous deletion of Rb. This requires further
clarification with epigenetic analysis.

The second feature determined using frequency plot analysis
was a high incidence of amplification along a limited chromosomal
region toward the centromere of chromosome 4, pointing to the
Met locus. A region spanning 80 Mb from the centromere of rat
chromosome 4 is syntenic to human chromosome 7. Various
human cancers, such as glioblastoma [50] and non-small cell lung
cancer [51], are reported to harbor amplifications in chromosome
7. Tyrosine kinase MET is a receptor for a hepatocyte growth
factor and is situated upstream of ras in the signal transduction
pathway, thus serving as an advantage for cell proliferation [52].
Therefore, it is conceivable that tumor size was proportionally
associated with the Met expression level (Figs. 3C and 4A).
Because we dissect the animal as soon as we recognize the tumor,
we believe that large-sized tumors are more aggressive in nature.
It is of note that tumor size was also related to the genome alteration
pattern (Fig. 4B), and was associated with amplification and
overexpression of Zbtb38 located on chromosome 8 (Fig. S4).
ZBTB38 (CBZ) represses the transcription of methylated
templates [53], thus presumably regulating epigenetic mechan-
isms. Down-regulation of ZBTB38, a novel substrate of caspase-3,
induces apoptosis [54] and this gene is localized in a prostate
cancer susceptibility locus [54]. These results confirm the
possibility of tumor classification using array-based CGH. Met
arose evolutionally late and is unique to mammals [52]; it could
thereby be associated with the unique amplification in the whole
genome.

Genomic amplification is hypothesized to occur via the
breakage-fusion-bridge cycle [55,56,57]. A Fenton reaction causes
double-stranded DNA breakage [10]. Our results revealed that
these amplifications consisted of a mixture of wide-range low-level
amplifications and fragmented, narrow high-level amplifications.
(Fig. 3A). This suggests a mechanism of positive feedback for amplification, starting from wide-range low-level amplification. We suspect an involvement of double-minutes, and a presence of susceptible genomic loci. This hypothesis requires further study. It was interesting that two tumor suppressive genes, Cdc1 [50,59] and ST7 [60], surrounded the Mst locus (Fig. 3B). This may be the reason why the Mst locus was a denominator for the rat RCCs. Whole exome or genome sequencing may further reveal new findings regarding point mutation and chromosomal translocation. Finally, we compared the present rat results with corresponding human tumors by transforming data based on chromosomal synteny (Figs. 5A and 5B). It was expected that the genomic alteration of Fe-NTA-induced rat RCC was most similar to human RCC presumably because target cells are the same. However, surprisingly, human mesothelioma was the second most similar. It is now established that most human mesothelioma results from exposure to asbestos, and the primary pathogenic process involves iron overload [8,61]. The same mesodermal origin of renal tubular cells and mesothelial cells may cause the similarity of the array-based CGH profiles. Endodermal tumor, such as pancreatic ductal adenocarcinoma (PDAC), and ectodermal tumor, such as glioblastoma multiforme (GBM), exhibited a significant difference in genomic profiles.

In conclusion, we showed that repeated Fenton reactions in wild-type rats induced cancer that recapitulated genomic alterations similar to those in human cancers, suggesting the involvement of oxidative stress as a major factor in human carcinogenesis. In this renal carcinogenesis model, preferred alterations were deletion; Cilla2A/2B deletion and Mst amplification were the major target gene modifications. A comparative interspecies analysis would contribute to identifying candidate carcinogenic agents.

Materials and Methods

Fe-NTA-induced Renal Cell Carcinoma Model

Fe-NTA-induced carcinogenesis experiments were performed using male F1 hybrid rats that were a cross between Fischer 344 and Brown-Norway inbred strains (Charles River, Yokohama, Japan) as previously described [62]. Thirteen RCC cases were used in this study, and the histological grade of the tumor was determined according to the modified World Health Organization classification as we previously described [62]. The details are summarized in Table 1. The animal experiment committees of the Graduate School of Medicine, Kyoto University Graduate School of Medicine and Nagoya University Graduate School of Medicine approved this study. FRCC001 and FRCC562 cell lines were established from primary Fe-NTA-induced RCCs as previously described [63].

Human Data

We used human array-based CGH data of pancreatic ductal adenocarcinoma (hPDAC) [28], T-cell acute lymphoblastic leukemia (hTALL) [28], glioblastoma (hGBM) [66], mesothelioma cell line (hMM) [67] and renal cell carcinoma (hRCC) [36]. The Agilent CGH-array data of the former four types of human cancer were obtained from NCBI’s Gene Expression Omnibus (GEO) website (http://www.ncbi.nlm.nih.gov/geo/). The GEO accession numbers for the data sets are GSE7599 (hPDAC), GSE7603 (hTALL), GSE9177 (hGBM) and GSE22237 (hMM). The human RCC data was obtained through analyses with BAC microarrays (4,361 clones) [68]. We defined similarity index between the two array-based CGH profiles as follows. First, we calculated the correlation coefficient with log2 ratios of the estimated copy number over the inferred cancer ploidy for the genomic positions corresponding to all of the Agilent 44 K human CGH microarray probes. Then, we multiplied the value by 1×103 after changing the absolute value into its square root.
