Analyses of cellular processes in the yeast *Saccharomyces cerevisiae* rely primarily upon a small number of highly domesticated laboratory strains, leaving the extensive natural genetic diversity of the model organism largely unexplored and unexploited. We asked if this diversity could be used to enrich our understanding of basic biological processes. As a test case, we examined a simple trait: the utilization of di/tripeptides as nitrogen sources. The capacity to import small peptides is likely to be under opposing selective pressures (nutrient utilization versus toxin vulnerability) and may therefore be sculpted by diverse pathways and strategies. Hitherto, dipeptide utilization in *S. cerevisiae* was solely ascribed to the activity of a single protein, the Ptr2p transporter. Using high-throughput phenotyping and several genetically diverse strains, we identified previously unknown cellular activities that contribute to this trait. We find that the Dal5p allantoate/ureidosuccinate permease is also capable of facilitating di/tripeptide transport. Moreover, even in the absence of Dal5p and Ptr2p, an additional activity—almost certainly the periplasmic asparaginase II Asp3p—facilitates the utilization of dipeptides with C-terminal asparagine residues by a different strategy. Another, as-yet-unidentified activity enables the utilization of dipeptides with C-terminal arginine residues. The relative contributions of these activities to the utilization of di/tripeptides vary among the strains analyzed, as does the vulnerability of these strains to a toxic dipeptide. Only by sampling the genetic diversity of multiple strains were we able to uncover several previously unrecognized layers of complexity in this metabolic pathway. High-throughput phenotyping facilitates the rapid exploration of the molecular basis of biological complexity, allowing for future detailed investigation of the selective pressures that drive microbial evolution.

Introduction

Our understanding of the inner workings of eukaryotic cells owes much to the yeast *Saccharomyces cerevisiae*. The application of powerful genetic and molecular tools to this model organism has yielded an extensively annotated proteome. These analyses have benefited greatly from the genome of experimentally tractable strains of *S. cerevisiae*, but an unintended consequence of this focus has been a tendency to ignore the vast wealth of natural genetic variation found in diverse strains of this organism. Following the “gold rush” ushered in by the sequencing of the *S. cerevisiae* genome, efforts are being made to revisit this natural diversity. Phenotypic analyses of diverse yeast strains [1,2] and the application of microarray technology to the analysis of allelic variation [3–8] and population genetic variation in gene expression [9–11] are providing new insights into the ecology and diversity of the species. Such analyses should also be applicable to the elucidation of pathways that face strong diversifying selection, such as those governing uptake and metabolism of nutrients. As a test case, we employed high-throughput phenotyping of diverse *S. cerevisiae* strains to dissect the multiple activities contributing to the utilization of di/tripeptides as a nitrogen source.

The capacity to import small peptides is a ubiquitous cellular function, found in bacteria, fungi, plants, and animals [12–16]. Although small peptides have clear nutritional value as a source of amino acids, carbon, and nitrogen, they can have additional beneficial functions. For example, studies in bacteria have demonstrated a link between peptide transport and chemotaxis [17], sporulation [18,19], and the recycling of cell wall peptides [20].

Peptide transport systems, however, can also be a source of biological vulnerability. A variety of antimicrobial and antifungal agents utilize the di/tripeptide transport machinery to gain entry into the cell [21,22]. Thus, the benefits and risks associated with peptide import represent conflicting evolutionary pressures that may help shape the regulation and substrate specificity of peptide transporters. In a similar vein, transporters of small peptides are also of great interest for their medical applications, as routes for delivery of peptidomimetic drugs [23,24].

Members of the PTR family of peptide transporters transport a variety of substrates, including nitrates, amino acids, and di/tripeptides [12,25]. All PTR members contain 12 predicted transmembrane helices, and transport a variety of...
Synopsis

Model organisms have allowed researchers to characterize basic biological processes in exquisite detail. Homann et al. suggest that this knowledge base presents a unique opportunity to exploit the natural genetic variation found in diverse isolates of the same species to gain new insights. Using high-throughput technology to assay growth, Homann et al. found that laboratory strains, vineyard isolates, and clinical isolates of the yeast Saccharomyces cerevisiae exhibit very different capacities to utilize di/tripeptides as nutrient sources. This led to the discovery of new di/tripeptide utilization activities and an elaboration of their specificities. Variations in the strength of these activities determine the spectrum of di/tripeptides that are preferentially utilized in a given strain. In turn, this influenced the vulnerability of these strains to a toxic peptide, which exploits the transport machinery to gain entry into the cell. This raises the intriguing possibility that opposing selective pressures, in which the benefit of utilizing di/tripeptides as a nutrient source is offset by the risk of importing toxic peptides, may have shaped the observed natural diversity. The natural genetic diversity present among isolates of model organisms augurs a rich resource for revealing complexities in molecular pathways and exploring the selective pressures that shaped them.

substrates by means of proton-motive force [26,27]. Although many organisms, such as humans and plants, contain multiple PTR2 family members, the yeast S. cerevisiae contains only one, the di/tripeptide transporter Ptr2p. The regulation of PTR2 expression in S. cerevisiae is strongly influenced by the composition of the extracellular environment. PTR2 expression is induced in the absence of preferred nitrogen sources [28]—even more so when the medium contains particular amino acids [29]. Import of di/tripeptides containing basic or bulky hydrophobic N-terminal residues also induces PTR2 by reducing cellular levels of the PTR2 repressor Cup9p. Specifically, these di/tripeptides serve both as ligands and as regulators of the E3 ubiquitin ligase Ubr1p, which mediates a protein degradation system that is governed by the identity of N-terminal amino acids [30,31] (Figure 1). These peptides are too small to serve as targets for degradation by the proteasome, and they are assimilated as nutrients via other peptidases in the cells. However, di/tripeptides with basic (Type 1: Arg, His, or Lys) and bulky (Type 2: Ile, Leu, Phe, Trp, or Tyr) N-terminal amino acids can compete with larger protein substrates for binding at the Type 1 and Type 2 Ubr1p substrate-binding sites. Upon binding, these peptides allosterically activate Ubr1p-mediated degradation of Cup9p by release of the Ubr1p auto-inhibitory domain, thus exposing a substrate-binding domain that binds an internal degron in Cup9p [32]. Relief of Cup9p repression of PTR2 results in enhanced PTR2 expression. This initiates a positive regulatory feedback loop in which di/tripeptide uptake perpetuates Ubr1p-mediated degradation of Cup9p, up-regulation of PTR2, and additional di/tripeptide uptake [32–34].

Investigations of di/tripeptide import in S. cerevisiae have typically been limited to the analysis of a small number of substrates through complementation of auxotrophies or the use of radiolabeled dipeptides. The development of the Biolog (Hayward, California, United States) system of Phenotype MicroArrays (PM) [35–37] provides the opportunity to dramatically expand the scope of these analyses. The

PM system facilitates the classification of bacterial and fungal species by generating a characteristic phenotypic profile, which reflects the metabolic capabilities and chemical sensitivities of different species. The strong representation of peptides in the PM assay plates—284 of the 400 possible dipeptide permutations and 11 tripeptides—provides a unique opportunity to assay the capacity of different S. cerevisiae strains to import and utilize di/tripeptides as nitrogen sources.

Using high-throughput data from PM assays, we uncovered extensive variation in dipeptide utilization in different strains of S. cerevisiae. We exploited this variation to uncover a diversity of strategies that may serve to balance the opposing selection pressures of nutrient utilization and toxin vulnerability. We find that Ptr2p provides only one of at least four distinct molecular activities that facilitate the utilization of dipeptides in S. cerevisiae. The varying strengths of these activities in different strains were key to their identification. No single strain would have revealed the full complexity of dipeptide utilization, underscoring the importance of natural genetic variation for developing a comprehensive understanding of cellular processes. We suggest that the compar-
ison of genetically diverse strains will provide many new avenues for exploring the malleability of basic cellular functions and the evolutionary mechanisms and selective pressures that shape complex traits.

Results

To advance our understanding of the processes contributing to nitrogen utilization in *S. cerevisiae*, we studied a panel of strains isolated from several widely differing growth environments (Table 1). We included two related laboratory strains, S288c and W303, two California vineyard isolates, RM3 and RM8, a vineyard isolate thought to be of French origin, Y55 [38], and a clinical isolate, YAT7. Because expression of the dipeptide transporter PTR2 is strongly induced by even micromolar amounts of certain amino acids supplemented in the media [29], we first restored all of these strains to full amino acid prototrophy (see Materials and Methods).

Assaying Nitrogen Source Utilization in Diverse Strains Using PM Assays

We utilized the PM system to assay the ability of these strains to utilize an extensive selection of dipeptides and other compounds as nitrogen sources. Cells were grown in 96-well plates in which each well contained a different nitrogen source. A proprietary tetrazolium dye solution, which is reduced to the purple compound formazan, was included in each well. Plates were photographed every 15 min, generating a growth curve for each well that primarily reflected dye reduction [39]. The remaining growth signal was attributable to turbidity resulting from cell growth.

Because the technology was developed for bacterial cells, we first asked how well the PM signal curves reflect yeast cell growth and respiration, and how reproducible these phenotypes were in standard yeast laboratory media. Reduction of the tetrazolium dye ostensibly results from cellular respiration [39], but when we tested petite strains of *S. cerevisiae* in the PM assay, they remained capable of robust dye conversion (data not shown). Thus, mitochondrial respiration is not required to produce reductants for this dye. Next, we employed dye-independent measures of growth, such as measuring optical density of PM plates lacking the tetrazolium dye and plating serial dilutions of cells from PM plates to solid media to measure the number of colony-forming units in each PM well. Dye conversion correlated well with growth (see Materials and Methods), except that dipeptides containing the amino acids histidine, lysine, and/or cysteine sometimes caused dye reduction in the absence of growth (data not shown). Interestingly, this growth-independent dye reduction occurred only in the presence of cells. Since it reflects an unknown metabolic process, these dipeptides were omitted from our analyses. It should be noted, however, that this growth-independent dye reduction exhibited strong inter-strain variation, suggesting yet another source of metabolic variation for further study.

The PM assay utilizes a viscous medium that supports less-vigorous growth than typical laboratory media (data not shown). To determine if growth on diverse substrates in PM plates correlates well with standard laboratory media, we assayed growth on dipeptides as the sole nitrogen source in both solid and liquid standard media (see below), using optical density at 600 nm to measure growth in the liquid assays. Given the sensitivity of the dipeptide transport machinery to environmental cues, it is unsurprising that some differences were observed between these platforms. In large part, however, these differing growth conditions provided similar results, and the reproducibility on all tested media was robust.

High-Throughput Phenotyping and Diversity

Next, we asked if the natural diversity in our yeast strains produced phenotypic diversity in nitrogen source utilization. The 48-h PM growth curves for each strain on each medium are provided in the supplemental materials (Dataset S1–S3). To simplify comparisons, each growth curve was assigned a score reflecting the extent of growth, as shown for representative curves in the legend of Figure 2 (see also Materials and Methods). In agreement with an earlier study of the ability of individual amino acids to serve as nitrogen sources in *S. cerevisiae* [40], we found that cysteine, histidine, and lysine did not support growth in any of our strains (Figure 2A). These are the same amino acids that, when present in dipeptides, caused some strains to reduce the tetrazolium dye in the absence of growth. Apart from some inter-strain variation in growth on glycine and tyrosine, the remaining amino acids supported robust growth in all strains tested.

In contrast to the general uniformity in the utilization of individual amino acids, the six strains we analyzed had very different patterns of dipeptide utilization. To assist visualization of the data, dipeptides were separated into two classes: N-end rule dipeptides, which up-regulate PTR2 by enhancing Ubr1p-mediated degradation of the Cap90p repressor (Figure 2B), and non-N-end rule dipeptides (Figure 2C). The clinical isolate YAT17 utilized the broadest spectrum of dipeptides (see Figure 2C in particular) and tripeptides (Figure 2D). Indeed, it grew robustly on many peptides that none of the other strains could utilize well, if at all. (Preliminary analyses of two additional clinical isolates, YAT17 and YAT21, suggest that robust di/tripeptide transport may be a common feature of strains adapted to the atypical mammalian host environment; data not shown.) The laboratory strain W303 utilized the fewest dipeptides. It lacked the broad capacity for N-end rule dipeptide utilization characteristic of the other strains (Figure 2B), but it did grow robustly on some of these dipeptides. In contrast, growth of the French vineyard isolate Y55 was limited on the non-N-end rule dipeptides in...
comparison to the other strains tested (Figure 2C). Each strain also exhibited a unique pattern in the utilization of other nitrogen sources (Figure 2D and 2E).

Given the close relationship between W303 and S288c (W303 was derived in part from crosses with S288c; R. Rothstein, personal communication), it was surprising that the PM profiles of S288c more closely resembled those of the California vineyard isolates RM3 and RM8. However, S288c and W303 did share two characteristics: Both grew robustly on all of the dipeptides in the array that contained C-terminal asparagine residues (Figure 2B and 2C, boxes with red borders), and both grew well on D-asparagine (Figure 2E).

**Figure 2.** Variation in Nitrogen Source Utilization among Six Strains of *S. cerevisiae*

Each square represents the growth of one strain in the PM assay supplied with the indicated nitrogen source. The value reflecting the extent of growth was generated from the 48-h signal curve of the PM assay and represented by the intensity of coloration, as shown in the legend. All signal values exceeding 200 reflected very robust growth, and are therefore represented with the same color. Blue-bordered squares denote nitrogen sources that produced varying results in that strain, exhibiting substantial variation in signal among replicates ($r^2$/mean > 10 and at least one replicate with signal $>50$ or $<200$). Red-bordered squares denote putative substrates of the Asp3p asparaginase.

(A) Amino acids, (B) N-end rule dipeptides, (C) non–N-end rule dipeptides, (D) tripeptides; amino acids are represented as single letters, and (E) miscellaneous nitrogen sources.

**Overexpression of PTR2 Masks Inter-Strain Variation and Enhances Di/Tripeptide Utilization**

The diversity of dipeptide-utilization traits suggests profound differences in the underlying mechanism of di/tripeptide import among our conspecific strains. One likely source of inter-strain variation in dipeptide utilization is differences in *PTR2* regulation. If dipeptide utilization is limited by low levels of Ptr2p, up-regulation of *PTR2* should enhance growth. To determine how broadly a lack of *PTR2* expression limits dipeptide utilization, we eliminated the repressor of *PTR2*, Cup9p, in three strains whose wild-type
dipeptide-utilization profiles were robust, intermediate, and weak: YAT7, RM8, and W303, respectively.

In all three strain backgrounds, the CUP9 deletions caused robust growth on most of the di/tripeptides present in the arrays (Figure 3). Even dipeptides that had not supported growth in any of the wild-type strains, such as dipeptides bearing the N-terminal acidic residues aspartate or glutamate, supported growth upon deletion of CUP9 (Figure 3B). Of the 197 dipeptides amenable to PM analysis, only a small fraction—most notably Trp-Trp, Trp-Glu, Asp-Asp, and Pro-Pro—supported little growth in the cup9Δ strains. These dipeptides may either be refractory to transport or less amenable to use as a nitrogen source following transport. The robust dipeptide utilization phenotype of the cup9Δ mutants indicates that Ptr2p is capable of transporting a very broad array of di/tripeptides, a property that has long been assumed but never addressed with such a large spectrum of dipeptides.

Further, the robust dipeptide-utilization phenotypes of the cup9Δ mutant strains indicate that differences in regulatory control of PTR2 are a key feature of the natural diversity observed among the strain backgrounds. Whereas the wild-type strains exhibited different dipeptide-utilization phenotypes (see Figure 2B and 2C), relief of PTR2 repression by deletion of CUP9 eliminated almost all inter-strain variation (Figure 3). Thus, the limited capacity for dipeptide utilization in wild-type W303 relative to RM8 and YAT7 is likely to reflect a difference in PTR2 regulation rather than a difference in Ptr2p function.

Ptr2p Is Not Required for the Utilization of Some Dipeptides

The only known transporter of di/tripeptides in S. cerevisiae is Ptr2p. Therefore, we expected that ptr2Δ strains would be unable to utilize any di/tripeptides in the PM assay. Surprisingly, this was not the case, particularly for non–N-end rule di/tripeptides (Figure 3B and 3C). All three strains tested did not require PTR2 to utilize a subset of these non–N-end rule dipeptides. Indeed, the W303-ptr2Δ mutant grew just as well as the wild-type strain on the non–N-end rule dipeptides.

When examined as a whole, these observations suggested that at least two activities contribute to dipeptide utilization: Ptr2p-mediated transport and an as-yet-unidentified activity. For N-end rule dipeptides, Ptr2p was the main activity contributing to their utilization, as evidenced by the almost complete abrogation of growth on these nitrogen sources by the ptr2Δ deletions (Figure 3A). For non–N-end rule di/tripeptides, both Ptr2p and the Ptr2p-independent activity played roles in their utilization (Figure 3B). The contribution of Ptr2p to general dipeptide utilization varied from minimal, as observed with W303, to substantial, as observed with the clinical isolate YAT7 (Figure 3, compare wild-type and ptr2Δ strains). In contrast, the similar growth properties of the ptr2Δ strains suggested that the contribution of the Ptr2p-independent activity was similar in all three strain backgrounds.

Dal5p Confers a Ptr2p-Independent Dipeptide-Utilization Activity

To identify the source of dipeptide utilization in the ptr2Δ strains, we took advantage of the robust growth of the W303-ptr2Δ strain when Ala-Leu was the sole source of nitrogen in the PM assay. We speculated that the concentration of Ala-Leu needed to support growth would be reduced if the gene allowing its utilization was overexpressed. Accordingly, we screened a high-copy (2 μm) genomic library for plasmids that restored growth of W303-ptr2Δ on limiting quantities of Ala-Leu (0.75 mM). After eliminating candidates that contained the PTR2 open reading frame, the three remaining plasmids were sequenced. Each plasmid carried the allantoate/ureido-succinate permease gene DAL5.

To analyze the contribution of Dal5p to basal dipeptide utilization, we constructed ptr2Δ, dal5Δ, and ptr2Δdal5Δ mutants in a variety of strain backgrounds. We began by testing the growth of serially diluted cells on conventional solid media containing different nitrogen sources (Figure 4). These included the putative Dal5p substrate Ala-Leu, as well as Tyr-Ala and Ala-Tyr, which had not supported growth of the ptr2Δ mutant in any of the strains tested in the PM assay (see Figure 3A and 3B). In all strains tested, the ptr2Δdal5Δ double mutant abolished growth on all three assayed dipeptide sources. Thus, utilization of these dipeptides required one of these two systems.

In the case of the dipeptides Ala-Tyr and Tyr-Ala, utilization was mediated by Ptr2p. Growth on these dipeptides was abolished by deletion of PTR2 alone, whereas deletion of DAL5 alone had no apparent effect. In contrast, the utilization of Ala-Leu involved both Ptr2p and Dal5p, but the relative contributions of these two activities varied between strains. Similar results were obtained using both solid (Figure 4) and liquid media (2 mM Ala-Leu; Figure S1). Ala-Leu could be utilized in strains RM8 and YAT17 via either Ptr2p or Dal5p, but Ptr2p was necessary and sufficient for wild-type growth levels. Strains W303 and Y55 did not exhibit this functional overlap in Ala-Leu utilization. W303-ptr2Δ grew as well as wild-type W303 on Ala-Leu, but W303-dal5Δ was completely unable to grow. In Y55, the same deletions created the opposite effect: Y55-ptr2Δ could not grow, whereas Y55-dal5Δ grew as well as wild-type Y55. Thus, Y55 relied upon Ptr2p for utilization of the assayed dipeptides, whereas W303 relied predominantly on Dal5p.

The Scope of the Contribution of Dal5p to Di/Tripeptide Utilization

Next, we used the PM assay to determine how many di/tripeptides could be utilized as nitrogen sources through the activity of the DAL5 gene. The gene was subcloned into a clean 2-μm vector, from the original plasmid that was isolated from the genomic screen, and tested in strain W303-ptr2Δ. Unlike the effect of overexpressing PTR2 (in the cup9Δ strain), the multi-copy DAL5 plasmid only enhanced growth on a small number of di/tripeptides (Figure 5). With the exception of Tyr-Glu, these di/tripeptides were all non–N-end rule dipeptides. N-terminal alanine, glycine, and serine residues were particularly favorable to Dal5p-mediated growth.

To determine whether Dal5p activity was redundant or supplemental to that of Ptr2p, the specific contribution of Dal5p to di/tripeptide utilization was explored using PM assays of the strains Y55-dal5Δ and RM8-dal5Δ (full data presented in Figure S2). In the case of Y55, deletion of DAL5 had negligible impact upon dipeptide utilization (Figure S2B and Figure 4). Because the strongest growth defect in wild-type Y55 was in the utilization of those non–N-end rule dipeptides that we have found to depend on Dal5p, we
speculated that Y55 might lack Dal5p activity. This hypothesis was verified by a PM assay of Y55-ptr2Δ. Unlike our earlier assays of ptr2Δ mutants in YAT7, RM8, and W303, deletion of PTR2 in Y55 completely eliminated growth on all dipeptides and tripeptides (Figure S2). Thus, Y55 relies solely upon Ptr2p for the transport of dipeptides.

In contrast, Dal5p contributed substantially to the utilization of dipeptides in RM8. All of the dipeptides that supported more robust growth in the presence of Dal5p belonged to the non–N-end rule category, and the majority contained the small N-terminal residues alanine or glycine (Figure 6 and data not shown). Deletion of DAL5 in strains RM8 and W303 did not significantly affect the utilization of any non-peptide nitrogen sources, except that growth was eliminated on N-acetyl-L-glutamate, an intermediate in arginine biosynthesis [41] (Figure S2C). (The fact that N-acetyl-L-glutamate utilization is an indicator of Dal5p activity explains why wild-type Y55 cannot utilize this substrate; see Figure 2E.) Clearly, DAL5 makes an important contribution to dipeptide utilization in yeast, and variations in DAL5 activity contribute to the naturally occurring variation in nitrogen utilization in diverse strains.

Elimination of Ptr2p and Dal5p Uncovers Additional Dipeptide-Utilization Activities

To determine whether Ptr2p and Dal5p account for all dipeptide utilization in the PM assays, we analyzed ptr2Δdal5Δ double mutants in two strains: W303, which showed the greatest dependence on Ptr2p-independent mechanisms, and RM8, which relied heavily upon both Ptr2p and Dal5p (Figure S2). In both strains, deletion of these two genes abolished all growth on most tested dipeptides and tripeptides. The most notable exception was that W303-ptr2Δdal5Δ, but not RM8-ptr2Δdal5Δ, retained the capacity to utilize all dipeptides with C-terminal asparagine residues (Figure S2; boxes with red borders). The obvious candidate for the underlying molecular determinant of this activity is the periplasmic asparaginase II (see Discussion). Since this protein is encoded by four copies of the ASP3 gene interspersed among rRNA and Ty loci in the genome, the origin of the phenotype was not amenable to genetic analysis.

A second strong exception to the requirement for Ptr2p and Dal5 was the utilization of Met-Arg by RM8, which was actually enhanced by the dal5Δ mutation (Figure 6) and remained robust in the ptr2Δdal5Δ double mutant (Figure S2).
Similar analyses of YAT7, W303, and Y55 mutants (Figure S2B and data not shown) indicated that the ability to robustly utilize Met-Arg in the absence of Ptr2p and Dal5p function was unique to RM8. Closer examination of the PM assay plates revealed that this Ptr2p- and Dal5p-independent activity might affect the utilization of other dipeptides as well. When PM assay plates containing RM8-\(\text{ptr2}^-\)\(\text{dal5}^-\) were incubated at 30°C for an additional 1 to 3 d following the PM assay, growth was seen in wells containing other dipeptides—specifically, those with C-terminal arginine residues (data not shown). This delayed-growth phenotype did not require the function of Dal5p or Ptr2p and was not observed in plates containing either W303-\(\text{ptr2}^-\)\(\text{dal5}^-\) or Y55-\(\text{ptr2}^-\). Thus, it represented a fourth distinct dipeptide utilization activity.

Inter-Strain Variation in Sensitivity to the Toxic Dipeptide Ala-Eth

The benefit of efficient utilization of diltipeptides as a nutrient source is likely to be counterbalanced by the vulnerability associated with indiscriminate peptide transport. To assay inter-strain variation in vulnerability to toxic peptides, the panel of diverse \textit{S. cerevisiae} strains was exposed to a dipeptide containing L-ethionine (Eth), a toxic methionine analogue (Figure 7). The purine derivative allantoin was provided as a nitrogen source [42] to eliminate the nutritional requirement for dipeptide uptake. Discs containing different concentrations of Ala-Eth were applied to lawns of cells, creating gradients of dipeptide concentration. Thus, the diameter of the halo of growth inhibition surrounding a disc is an indicator of dipeptide import.

In the standard halo assay, minimal medium with allantoin (MMA) is supplemented with 30 \(\mu\)g/ml leucine to induce \(\text{PTR2}\) expression (MMA + Leu medium). Under these conditions, wild-type strains varied substantially in sensitivity to Ala-Eth toxicity (Figure 7). S288c was the most sensitive to the dipeptide, whereas W303 was completely resistant. In the absence of the leucine inducer, only the clinical isolates YAT17 and YAT21 were sensitive to Ala-Eth (Figure 7).

Deletion of \(\text{PTR2}\) alone was sufficient to confer complete resistance to the toxic dipeptide under the conditions tested (RM8-\(\text{ptr2}^-\) and YAT7-\(\text{ptr2}^-\) were tested; data not shown). While this might suggest that Ptr2p is the primary transporter of Ala-Eth, we note that Dal5p may also transport allantoin [43,44], raising the possibility that allantoin competes with Ala-Eth for Dal5p-mediated uptake. Indeed, Ala-Met, which is structurally similar to Ala-Eth, supports growth in \(\text{ptr2}^-\) strains.

Figure 5. Utilization of a Subset of Dipeptides Is Enhanced in W303-\(\text{ptr2}^-\) upon Overexpression of DAL5

Strain W303-\(\text{ptr2}a\) was transformed with either the vector pRS426 or the plasmid pRS426-DAL5, a 2-\(\mu\)m plasmid containing a genomic fragment including DAL5, and phenotyped using the PM assay. The nitrogen sources shown comprise all instances in which the signal values met our reliability criteria (see Figure 2) and the presence of pRS426-DAL5 altered the signal value by more than 50 units relative to the vector control. Dipeptides followed by \(''(2x)''\) are present in the PM assay plates at twice the concentration of the other dipeptides.

DOI: 10.1371/journal.pgen.0010080.g005

Figure 6. Deletion of DAL5 in Strain RM8 Strongly Affects the Utilization of a Subset of Assayed Dipeptides

All instances in which RM8 and RM8-\(\text{dal5}^-\) signal values differ by more than 50 units and conform to our reliability criteria (see Figure 2) are presented. Dipeptides followed by \(''(2x)''\) are present in the PM assay plates at twice the concentration of the other dipeptides.

DOI: 10.1371/journal.pgen.0010080.g006

Figure 7. Halo Assay for Uptake of the Toxic Ala-Eth Dipeptide

Cells were plated onto MMA with or without 30 \(\mu\)g/ml leucine, an inducer of \(\text{PTR2}\) expression. Halo diameters in the presence of discs containing the indicated Ala-Eth concentrations are presented as the mean \(\pm\) standard deviation. (\(\text{ptr2}^-\) strains were also tested, and exhibited no halos.)

*aHalo boundary was indistinct, often slowly receding as cells closer to the disc began to grow.

DOI: 10.1371/journal.pgen.0010080.g007
strains (see Figure 3B) and dal5Δ strains (Figure S2B), suggesting that Dal5p and Prr2p both contribute to the vulnerability of yeast cells to Ala-Eth.

Elimination of the PTR2 repressor Cup9p enhanced Ala-Eth sensitivity in all strains tested, yet it also revealed additional diversity among the strains (Figure 7, cup9Δ). The resistance of strain W303 to Ala-Eth was overcome by the cup9Δ mutation to the extent that the W303-cup9Δ mutant exhibited higher sensitivity to Ala-Eth than cup9Δ mutants of either RM8 or YAT7. All of the cup9Δ mutant strains exhibited some sensitivity to Ala-Eth in the absence of the leucine inducer. Curiously, despite the robust dipeptide import characteristic of the YAT7 strain, YAT7-cup9Δ produced much smaller halos under these conditions than either W303-cup9Δ or RM8-cup9Δ (Figure 7, see also Figure 8). Some of the inter-strain variation observed in the halo assay might reflect varying sensitivity to ethionine. However, since both changes in media composition and the cup9Δ mutations affected strains differently, this diversity is clearly shaped by the complex regulatory controls governing dipeptide import.

**Expression and Localization of Prr2p Varies Substantially among Strains**

Strain W303 was both highly resistant to the toxic Ala-Eth dipeptide and limited in dipeptide utilization capacity. Therefore, we asked whether Prr2p expression in this strain differed from that of the other strains tested. To directly visualize the expression of Prr2p, a C-terminal FLAG-2xGFP-6xHis tag was added to the endogenous Prr2 gene of strains W303, RM8, and YAT7 by site-specific homologous recombination. These modified strains retained a similar capacity to utilize dipeptides (data not shown). To facilitate comparison of Prr2 expression with the results of the halo assay, expression of green fluorescent protein (GFP)-tagged Prr2 was assayed in a liquid version of the MMA and MMA+Leu media, and fluorescence was measured using a uniform exposure level (Figure 8; halo assay images included for comparison).

The presence of Prr2p at the plasma membrane correlated well with the extent of Ala-Eth toxicity observed in the halo assay (except that fluorescence was weaker in RM8 than might have been expected from its strong Ala-Eth sensitivity in MMA+Leu). In all other cases, conditions promoting strong Ala-Eth sensitivity also induced strong Prr2 expression. Strikingly, wild-type W303, which was resistant to Ala-Eth, exhibited virtually no Prr2p fluorescence. The cup9Δ mutation restored strong Prr2 expression and also restored Ala-Eth sensitivity. Thus, the resistance of W303 to Ala-Eth in the halo assay resulted from an absence of Prr2p at the plasma membrane. Moreover, these results confirm that W303 contains a functional Prr2 gene subject to atypical regulation.

**Additional Aspects of Prr2 Regulation**

Retrograde recycling of membrane-bound Prr2p is thought to represent an additional layer of regulatory control of
dipeptide import (H. Cai and J. Becker, unpublished data). Although GFP-tagged Prr2p was typically localized to the membrane, when strain RM8 was grown in YPD, additional fluorescent signal was also observed in the vacuole and in what appeared to be large vesicles. The high levels of PRR2 expression in the rich YPD media was itself surprising, since PRR2 is thought to be subject to nitrogen catabolite repression in the presence of preferred nitrogen sources [28]. Although YAT7 also exhibited robust PRR2 expression under these conditions, Prr2p was confined to the plasma membrane. This inter-strain variation was likely influenced by cellular Prr2p levels, as cap1Δ mutants of RM8, YAT7, and W303 all exhibited robust PRR2 expression and some intracellular Prr2p localization in YPD media (Figure 8). However, although wild-type RM8 and YAT7 both exhibited strong Prr2p fluorescence in YPD, only RM8 exhibited abundant intra-cellular compartmentalization of Prr2p, indicating that retrograde transport of Prr2p is yet another regulatory process that varies between strains in S. cerevisiae.

The regulation of PRR2 in W303 differed significantly from the other strains analyzed in this study. Considering the possibility that polymorphisms within the PRR2 promoter region may account for the limited PRR2 expression in W303, we sequenced an 899-base pair (bp) region immediately upstream of the PRR2 start codon in the strains W303, S288c, RM8, and YAT7 (Table S1). The promoter region in W303 differed from that of S288c at only one base, a C→T transition at position −799. However, this polymorphism was shared by the strain RM8, which unlike W303 is sensitive to Ala-Eth and exhibits robust PRR2-dependent utilization of N-end rule dipeptides. Thus, differences in promoter sequence are not a likely source for the altered regulation of PRR2 in W303.

Telomeric regions are common sites of epigenetic regulation, and PRR2 is located in proximity (~50 kb) to a telomere. In our analyses of GFP-tagged PRR2, a small subpopulation (1 in 50 to 1 in 1,000, depending on conditions) of strongly fluorescent W303 cells was consistently observed during growth in either the MMA+Leu medium or in YPD (Figure 8; inset). W303 cells exhibiting robust PRR2 expression also arose spontaneously at a high frequency (>0.1%) on solid media. These cells maintain competency for PRR2 expression following serial propagation on media that relieve selection for active dipeptide transport (J. Manjrekar and S. Lindquist, personal communication). These switching events were far too frequent to reflect mutation, suggesting that an epigenetic switch exists that can stably confer competency for PRR2 expression in W303 cells.

Discussion

Our results establish that the rich inter-strain diversity and genetic tractability of S. cerevisiae can be combined with high-throughput phenotyping to provide new insights into basic cellular processes. Using this approach, we have uncovered previously unrecognized functions and regulatory systems governing the utilization of dipeptides as a nitrogen source. The natural diversity in these systems included variation in sensitivity to a toxic dipeptide, suggesting that dipeptide utilization can be considered in the context of an adaptive landscape shaped by opposing selective pressures.

Using High-Throughput Phenotyping to Study Di/Tripeptide Utilization

The exploration of natural diversity using high-throughput phenotyping techniques has the potential for tremendous synergy with the existing high-throughput technologies that have shaped our understanding of the cellular circuitry of S. cerevisiae. The pursuit of an integrated understanding of yeast functional genomics and proteomics (reviewed in [45]) has been enabled by numerous powerful high-throughput approaches. For example, genetic networks have been elucidated by high-throughput screens for synthetic lethality [46], protein interaction networks have been mapped using mass spectrometry [47,48], and transcriptional networks have been elucidated by the now-ubiquitous technique of transcriptional profiling using microarrays and by the mapping of physical interactions between transcription factors and promoters [49]. The technology for global analysis of growth phenotypes remains largely underdeveloped and unexploited—despite the fact that it is phenotype that determines how cellular systems interface with selective pressures. Thus, the broad synthesis of our understanding of genomic, transcriptional, and phenotypic diversity is contingent upon the development of robust technologies for high-throughput phenotyping.

Here, we have tested one of the first such systems by assaying dipeptide and tripeptide utilization on a previously unfeasible scale. The PM phenotypic assay allows simultaneous testing of approximately 2,000 growth conditions, providing a tremendous savings in time and labor. The technology was typically very robust and provided reliable and reproducible data that were easily manipulated using the accompanying software. However, the PM technology also has several drawbacks that need to be addressed before this technology is broadly suitable for use by the yeast research community. Due to the initial design focus on generalized bacterial phenotyping, many of the available PM assay plates are not optimized for S. cerevisiae. Thus, the number of useful growth conditions is considerably less than 2,000. This issue is compounded by the high cost of the PM assay plates. Further, different batches of media and PM assay plates provided by the manufacturer often affected reproducibility. Such technical difficulties are not atypical for a new technology, and the power of such tools in exploring the phenotypic diversity of S. cerevisiae is clear. Hopefully, the importance of high-throughput phenotyping will lead to reduced costs and enhanced suitability of these technologies.

Uncovering Unexpected Complexity in Di/Tripeptide Utilization

Through extensive phenotyping, we found that Prr2p is but one component of a multifaceted system in S. cerevisiae governing the utilization of dipeptides as nitrogen sources. The discovery of these additional components was made possible by the dramatic inter-strain variation observed in the contributions of these activities to dipeptide utilization (summarized in Table 2). We have clearly identified one previously unknown component of this system—the allantoate/ureidosuccinate permease Dal5p—and have defined parameters of two others that suggest mechanistic explanations.

Of these four components, Prr2p exhibits the broadest dipeptide utilization activity. Relief of PRR2 repression by
deletion of CUP9 facilitated robust growth on nearly all di/tripeptides tested. This was even true of W303, which otherwise grew on only a limited subset of the N-end rule dipeptides that supported growth of the other wild-type strains. This restricted utilization of potential Ptr2p substrates provides a window into the complex PTR2 regulatory system. For example, one can ask why W303 is capable of growing on Trp-Arg, but not Arg-Trp (see Figure 3A), even though both are N-end rule peptides composed of identical residues. One possibility is that the N-end rule pathway in W303 is more responsive to Type 1 ligands (basic N-terminal residues; e.g., Arg) than Type 2 substrates (bulky hydrophobic N-terminal residues; e.g., Trp). Alternatively, substrate preference may arise from dipeptidase specificity [50] resulting in more robust hydrolysis of Trp-Arg upon import. Although beyond the scope of this analysis, additional insights and hypotheses can be derived from the wealth of data provided by our high-throughput analysis, and the approach developed here—the application of a diverse panel of strains to the PM assay to analyze di/tripeptide utilization—can be employed in future studies to enrich our understanding of PTR2 regulation and Ptr2p function.

Dal5p, a second component of the dipeptide utilization system, was previously identified as a permease for the pyrimidine biosynthetic precursor ureidosuccinate [51] and the nitrogen source allantoate [43]. Expression of DAL5 is subject to complex regulatory control by the nitrogen catabolite repression system [43,52,53]. It is therefore fitting that Dal5p also is involved in the utilization of dipeptides as a nitrogen source. With the exception of Tyr-Gln, all Dal5p di/tripeptide substrates belonged to the non-N-end rule class. Many of the dipeptides supporting growth in RM8-ptr2A (see Figure 3) did not support growth in RM8-dal5A (see Figure 6). Thus, Dal5p-mediated dipeptide transport is not redundant to that of Ptr2p, but rather a complementary activity that enhances the range of dipeptides that can be utilized.

A third component, evident in strains W303 and S288c, governs the utilization of dipeptides containing C-terminal asparagine residues as nitrogen sources (see Figure 2). Several lines of evidence support the conclusion that the Asp3p periplasmic asparaginase facilitates the utilization of these substrates. Asp3p activity is closely linked to nitrogen utilization. Nitrogen starvation has been demonstrated to up-regulate ASLP3 expression and promote the secretion of asparaginase II [54]. Furthermore, the enzymatic activity of asparaginase II hydrolyzes either L- or D-asparagine into ammonia and aspartate, facilitating the use of D-asparagine as a nitrogen source [55,56]. Of the strains tested, only W303 and the related laboratory strain S288c were able to utilize D-asparagine in the PM assay (see Figure 2E). Genomic analyses utilizing microarrays have noted a lack of detectable ASLP3 in Y55 [57] and a clinical isolate, YJM789 [3]. Neither Y55 nor our clinical isolate, YAT7, were capable of utilizing the putative Asp3p substrates (see Figure 2). Most important, the asparaginase of the bacterial plant pathogen Erwinia carotovora has been shown to deamidate C-terminal, but not N-terminal, asparagine residues of small peptides [58]. This specificity precisely matches the dipeptide utilization phenotypes observed for W303 and S288c. Both strains are unable to utilize the two dipeptides with N-terminal asparagine residues present in the PM nitrogen plates (see Figure 2B), but are able to utilize all dipeptides containing C-terminal asparagine residues (see Figure 2; boxes with red borders). To our knowledge, our study provides the first evidence for such an activity in S. cerevisiae, in which mechanisms of extracellular peptide processing are rare.

A fourth component of the dipeptide utilization system, evident in strain RM8 but not W303, governs the use of dipeptides containing C-terminal arginine residues, and Met-Arg in particular. Utilization of Met-Arg is clearly enhanced by deletion of DAL5 (see Figure 6) and persists in the ptr2dal5A double mutant (Figure S2), and thus represents another previously unrecognized mechanism of dipeptide utilization. Given the specificity for a nitrogen-rich C-terminal residue, an arginase activity comparable to the asparaginase activity of Asp3p would seem a likely candidate.

Balancing the Benefits and Potential Risks of Robust Di/Tripeptide Import

Variation in the relative strengths of the activities contributing to dipeptide import can strongly impact the range of dipeptide substrates utilized by the cell. Although di/tripeptides can serve as a valuable source of nutrients, evolutionary pressures opposing indiscriminate import may reinforce mechanisms promoting transport specificity. One such pressure might be the need to avoid import of antifungal agents that exploit the di/tripeptide transport machinery to gain entry into the cell (reviewed in [22]).

Of the di/tripeptide-utilization activities characterized in this study, the Pt2p transporter provides the means to transport the broadest spectrum of dipeptide substrates (see Figure 3), yet it is also the source of vulnerability to the toxic Ala-Eth dipeptide (see Figure 7). Thus, strains that exhibit robust PTR2 expression, such as the clinical isolate YAT7, efficiently utilize a broad spectrum of dipeptides as a nitrogen source (see Figure 2), but are also vulnerable to Ala-Eth toxicity (see Figure 7). In contrast, the limited PTR2 expression in strain W303 provides protection from Ala-Eth at the cost of a more limited capacity to utilize di/tripeptides. However, in certain growth conditions, a fraction of W303 cells exhibit robust PTR2 expression, suggesting a possible epigenetic mechanism for employing both high- and low-risk di/tripeptide utilization strategies in an isogenic population.

The optimal strategy for dipeptide utilization will vary between environments. For instance, in the presence of toxic peptidomimetics that resemble Dal5p substrates, strain Y55

A qualitative summary of the contributions of the dipeptide utilization activities observed in this study; "Yes" indicates activity is present; "-" indicates activity is minimal or absent; "ND", not determined due to insufficient data.
Prt2p activity was exceptionally robust in this strain.
Refers to the capacity to utilize dipeptides containing C-terminal arginine residues (particularly Met-Arg) in the absence of Ptr2p and Dal5p activity.
DOI: 10.1371/journal.pgen.0010080.t002
would have a significant fitness advantage over the other strains tested in this study, as it exhibits no detectable Da15p activity (Figure S2). In environments with a strong risk of exposure to a variety of toxic di/tripeptides, the risks of Ptf2p- and Da15p-mediated import may outweigh the potential nutritional benefits. In such cases, the utilization of a limited subset of di/tripeptides may represent a low-risk mechanism by which some nutritional benefit can be extracted from the available di/tripeptides. For example, extracellular release of ammonia from C-terminal asparagine residues by Asp5p would serve as a more limited, but risk-free, means of obtaining nitrogen from di/tripeptides. In contrast, in an environment in which nitrogen sources are scarce and the risk of importing toxic species is minimal, robust expression of PTF2 would be a beneficial trait. We note that the clinical isolates YA17 (see Figure 2), YA17, and YAT21 (data not shown) exhibit the most robust dipeptide utilization of the strains studied, perhaps reflecting the environmental pressures of the ecological growth environment in the human host. Further investigation into the ecology, population structure, and population genetics of S. cerevisiae would help future attempts to link phenotypic diversity to likely environmental pressures.

High-throughput phenotyping and genetic diversity can provide new insights into the genetic determinants governing adaptation to the nutritional and chemical challenges of diverse environments. Our study represents a first-case example of how this approach can be utilized to elucidate metabolic processes and provide a broader evolutionary context within which the observed natural diversity can be considered.

Materials and Methods

Media and reagents. Synthetic defined (SD),YPD, and 5-FOA (BioVec trypanosome) media were made using standard formulations [59]. When needed, G418 (Gibco, Carlsbad, California, United States) was added to the YPD medium at 200 μg/ml to select for Kan'. To select for HygB', Hygromycin B (American Bioanalytical, Natick, Massachusetts, United States) was added to YPD at 250 μg/ml. All dipeptides used outside of the PM assays were obtained from Bachem California (Torrance, California, United States). A minimal medium (MM), supplemented with the indicated nitrogen sources, was utilized for the Bioscreen C growth curve assays (Growth Curves USA, Piscataway, New Jersey, United States). MM contained 2% glucose, 0.17% yeast nitrogen base without (NH₄)₂SO₄ and amino acids (Qbiogene, Irvine, California, United States), 18 mg/l uracil (omitted for URA3 plasmid-bearing strains), and 2% agar (for solid media). The MMA used in the halo assay and GFP assays was identical to MM except that it contained 1 g/l allantoin as a nitrogen source and a slightly different concentration of uracil (20 mg/l). The Biolog PM media contained 50 mM glucose, 1 mM d湖泊四磷酸盐, 2 mM sodium sulfate, and a proprietary tetrazyan dye mix and IFY-0 medium. IFY-0 is a basal medium, lacking nitrogen, carbon, phosphate, and sulfur sources, which are supplemented as needed.

Plasmid construction. Construction of the pM2S plasmid is described in [60]. The plasmid pPTR2-2xGFP-SFH-KanR was constructed by addition of tandem copies of GFP (2xGFP) and a kan' selectable marker into plasmid pM2S. First, primers PTR2-FLAG-GFP-F and P2R2-FLAG-GFP-R (all primer sequences are supplied in Table S2) were used to amplify a 1.5-kb fragment containing 2xGFP from plasmid pUG6 [64] with a HphMX marker from pAG32 [65]. First, a PCR fragment containing the hphMX cassette was amplified from pAG32 using primers O-199 and O-200 and digested with Mulu and BsmI. The resulting fragment was then inserted into the similarly digested plhMX.

Strain construction. The source and origins of the strains used in this study are indicated in Table 1. To make all strains MATa ura3, some modifications were made to eliminate amino acid auxotrophies, mutate URA3, and change mating types in diploid (Protocol S1). All transformations were conducted using the standard lithium acetate technique [66].

PTR2 was deleted with a short-flanking homology (SFH) cassette amplified from plasmid pAG32 [65] (the case of V55; the GFP portion of the plasmid was not amplified). This deletion cassette replaced the PTR2 region spanning +77 to +1781, relative to the start codon, with a kanMX marker in the case of V55. CUP9 was deleted with a SFH cassette derived from plasmid pAG32 containing the hphMX marker from a SFH cassette amplified from pAG32. This deletion cassette eliminated the DAL5 region spanning +70 to +1594, relative to the start codon.

Addition of a FLAG-2xGFP-6xHis tag to the C-terminus of endogenous PTF2 was accomplished with a SFH cassette amplified from plasmid pPTR2-2xGFP-SFH-Kan-R. Proper integration was ensured by selection on G418 media and verification by colony PCR. Final confirmation of proper integration was obtained by observation of membrane-localized GFP fluorescence in MMA-Leu medium.

PM assays of nitrogen source utilization. A full list of the nutrient sources tested in the PM assay plates is provided in Dataset S4. Each well of the PM plates contains a very low micromolar amount of amino acids, at a level insufficient to complement auxotrophies or serve as an adequate nitrogen source. All dipeptides are present at the same concentration (between 1–4 mM), the precise concentration is proprietary information, with the exception of the small set of dipeptides present in PM03, which are present at double the concentration of the others. (These are noted as (2x) when presented in the figures.)

Strains were prepared for inoculation into the PM assay plates for use in the following survival assays. Glycerol stocks were streaked to YPD plates and incubated at 30° C for approximately 48 h. Next, two to three colonies from each strain were restreaked to one section of a fresh YPD plate and incubated overnight at 30° C. In the morning, cells on each YPD plate were spread over the plate to form a thin layer and incubated an additional 4–6 h to ensure that most cells were actively growing. To avoid excess inactivation, we also treated the late-growth clumping encountered with some wild strains. In the case of strains containing plasmids, standard SD-ura dropout plates were placed in use of YPD.

Cells were then inoculated into sterile water in 20 × 100 mm test tubes and adjusted to a transmittance of 63% (~5×10⁷ cells/ml). This 48% concentration cell suspension also contained 14.4 mM uracil, except when plasmids were used. The cell suspension was then reduced to 1X concentration by dilution into the Biolog PM media; 100 μl of this mix was then inoculated into each well of the PM assay plates PM03, PM06, PM07, and PM08. The plates were then sealed with sterile Oxygen SealPlate film (Union City, California, United States), placed in the OmniLog reader (Biolog), and incubated for 48 h at 30 °C. The OmniLog reader photographs the plates at 15-min intervals, converting the pixel density in each well to a value reflecting cell growth and dye conversion.

After completion of the run, the signal data were compiled and analyzed. Signal data were exported from the Biollog software, compiled using Microsoft Excel (Redmond, Washington, United States), and then visually represented using Java TreeView v1.0.8 [67] and Adobe Illustrator (San Jose, California, United States). We chose to export the average and maximum signal value for each well and then average the two values. In doing so, we were able to represent the full time course as a single number and weight the value towards latter time points. Shadows cast over perimeter wells in the OmniLog machine sometimes raised the basal signal level of these wells. This was accounted for by determining a “baseline” signal level for each well by calculating the average signal for all time points of the run. This value was then subtracted from the previously
calculated signal value, yielding a final signal value. These calculations can be summarized as follows:

\[
\text{Signal value} = \left( \frac{\text{average signal over 48 h} + \text{maximum signal over 48 h}}{2} \right) - \left( \text{average signal over first 2 h} \right)
\]

In all cases, a minimum of two replicate PM assay runs were conducted, and the average of the signal values was used. Additionally, when non-wild-type strains were assayed, two independently constructed deletion strains were always tested. The PM assay data used to generate the signal curves presented in this study are provided in Dataset S4. Images of all signal curves are provided in Datasets S1–S3.

To ensure that dye reduction was not occurring in the absence of growth, all MM plates were carefully examined following each run. The plates were inverted upon a light-box such that cells were visible in wells that supported growth. This approach revealed that dipeptides containing lysine, histidine, and cysteine residues, as well as the amino acid histidine, sometimes supported reduction of the dye in the absence of growth. (Dipeptides containing these residues were omitted from the analysis; see Results.) Two additional control measures were taken to ensure that the correlation between dye reduction and cell density was robust. First, the PM assay was conducted once with each wild-type strain in the absence of the tetrazolium dye. Second, several PM runs were plated as dilution series to YPD media at the conclusion of the 48-h run. These additional measures confirmed that, with the exceptions noted above, the PM assay signal is a reliable indicator of growth in the presence of the nitrogen sources discussed in this study.

**Bioscreen growth curve analysis.** A selection of PM assay dipeptide-utilization phenotypes were verified using a Bioscreen C (Growth Curves USA) plate reader. Strains were cultured as described for the PM assay, but were inoculated at an optical density at 955 nm (OD955) of 0.92 into MM supplemented with the indicated nitrogen source. The minimum amount of inoculum was adjusted to 100 micro-wells on a 96-well plate and incubated in the Bioscreen C at 30 °C with heavy shaking. Measurements of OD955 were made at 45-min intervals. Each growth curve was conducted in duplicate wells and was repeated at least once.

**Screen for Ptr2p-independent dipeptide utilization.** The screen was conducted using a pRS292-based genomic library (2 μm: URA3) containing Sau3AI-digested genomic DNA with an average insert size of 6–8 kb (gift of Dr. Gerald Fink; originally constructed by Connelly and Hieter from a strain congenic with S288c [88]). A full description of the screen can be found in Protocol S2.

**Halo assay of Alpha-Eth toxicity.** The sensitivity of deletion mutants to the toxic dipeptide Alpha-Eth was measured as previously described [29]. Ethionine (Eih) is an analog of methionine, and utilization of Eth causes cell death. The tested strains were grown overnight in MMA. Yeast cells were harvested and washed three times with sterile, distilled water, then counted and adjusted to 5 × 10⁶ cells/ml. One ml of the cell suspension was added to a 100-well plate incubated in the Bioscreen C at 30 °C with heavy shaking. Measurements of OD955 were made at 45-min intervals. Each growth curve was conducted in duplicate wells and was repeated at least once.

**Figure S1. Dal5p and Ptr2p Exhibit Strain-Dependent Contributions to the Utilization of Ala-Leu as a Nitrogen Source**

Wild-type, dal5Δ, ptr2Δ, and ptr2Δ/dal5Δ versions of the indicated strains were grown at 30 °C in liquid MM containing 2 mM Ala-Leu as the sole nitrogen source. A few time points were omitted because of technical difficulties with the Bioscreen C growth curve machine. Found at DOI: 10.1371/journal.pgen.0010080.g001 (2.8 MB JPG).

**Figure S2. Additional PM Signal Profiles Reveal the Varied Contribution of Dal5p to Dipeptide Import in Strains RM8, W303, and Y55**

Refer to Figure 2 for details on data analysis and presentation. The column label ptr2Δ (vector) refers to strain W303-ptr2Δ transformed with the high-copy (2 μm) vector pRS426. The column label ptr2Δ (DAL5) refers to strain W303-ptr2Δ transformed with plasmid pRS426-DAL5. Note that the PM assays presented in this figure utilized a more recent manufacturing lot of the PM nitrogen plates than those presented in the other figures. Different lots can produce subtle differences in signal magnitude. The wild-type RM8 and Y55 PM data presented here were derived from the same lot to facilitate direct comparison. Found at DOI: 10.1371/journal.pgen.0010080.g002 (631 KB PDF).

**Protocol S1. Construction of the Strains Used in This Study**

The source and origins of the strains used in this study are indicated in Table 1. Found at DOI: 10.1371/journal.pgen.0010080.s005 (39 KB DOC).

**Accession Numbers**

The Swiss-Prot (http://www.ebi.ac.uk/swissprot) accession numbers for

**GFP microscopy.** To test the localization of GFP-tagged Ptr2p, yeast strains carrying PTR2 with a C-terminal FLAG2×GFP-6×His tag were grown at 30 °C in MMA, MMA-ΔLeu, or YPD media. Yeast cells were collected during log-phase and imaged. The GFP signal was observed by fluorescence microscopy with a 470–490-nm excitation wavelength and 515-nm emission filter fitted to an Olympus microscope (Medvile, New York, United States). Both fluorescent and differential interference contrast (DIC) images were taken with a MicroFire camera (Model S99809; Olympus).

**Supporting Information**

**Dataset S1. PM Signal Curves for Data Presented in Figure 2**

Each image provides the signal curves generated by the OmniLog software in each well of the four 96-well plates that constitute the PM nitrogen source utilization assay (see Dataset S4 for full listing of plate contents). The x-axis of each signal curve represents the 48-h time course. The y-axis represents the signal intensity, an indirect measure of growth. The different colored lines used for the signal curves represent independent replications of the PM assay. Found at DOI: 10.1371/journal.pgen.0010080.s001 (2.1 MB DOC).

**Dataset S2. PM Signal Curves for Data Presented in Figure 3**

See Dataset S1 legend for details. Found at DOI: 10.1371/journal.pgen.0010080.s002 (2.2 MB DOC).

**Dataset S3. PM Signal Curves for Data Presented in Figure S2**

See Dataset S1 legend for details. Found at DOI: 10.1371/journal.pgen.0010080.s003 (3.1 MB DOC).

**Dataset S4. Raw Quantitative PM Data**

Contains data used to calculate signal values and a complete listing of the contents of the PM plates utilized in this study. Found at DOI: 10.1371/journal.pgen.0010080.s004 (805 KB XLS).
the genes and gene products discussed in this paper are ASP3 (P11165), Gapp9 (P41817), DAL5 (P13365), Prr2p (P32901), and Ubr1p (P19812).

Acknowledgments

We thank John McCusker, Barbara Garvik, Gerald Fink, and Rodney Rothstein for providing the strains utilized in this study. We are also grateful to Gerald Fink for the use of the C. Connolly and P. Hieter library and Fred Naider for the gift of A1a-Eth. We also thank Jessica Brown, Leah Cowen, Johannes Manjekar, and Todd Sanger for their critical reading of the manuscript. This work was supported by the Harold and Leila Y. Mathers Charitable Foundation.

Competing interests. The authors have declared that no competing interests exist.

Author contributions. ORH conceived and designed the experiments and data analysis, with important contributions from HC (A1a-Eth toxicity assays and QF imaging assistance). JMB assisted in reading the manuscript and advised in peptide transport. SLL provided research guidance and feedback on the manuscript. ORH wrote the paper with considerable feedback and guidance from SLL.
